Preface

Although the planet on which we live is called *Earth*, more than 70% of her surface is covered by the ocean. With the constant increase of human population, people are striving to develop more living space in the ocean and take advantage of its resources. However, there is no doubt that during this process humans will meet many technological challenges and must find ways to protect the ocean environment, on purpose of reaching a sustainable and harmonious lifestyle with the ocean. To achieve this goal, we must know the ocean, gather sufficient knowledge about the ocean, and treat the ocean in a respectful and cautious manner, because otherwise, any violent and reckless exploration behavior that harms the ocean will lead to unaffordable consequences to humanity. Therefore, to understand the ocean and to master the fundamental technology relating to its development is of critical importance, especially this year when humanity is truly beginning to experience the obvious temperature rise due to global warming.

The writing of this encyclopedia, *Ocean Engineering*, has three aims. Firstly, to provide a useful introductory reading reference for people interested in, but not delving into, the field of ocean engineering. Secondly, to provide necessary scientific and technological knowledge for people who are delving into some specific aspects in ocean engineering and want to do interdisciplinary extensions. Thirdly, to contribute within our scope in helping people find sustainable and harmonious ways to develop and protect the ocean.

This encyclopedia discusses the main categories of fundamental knowledge on ocean engineering, which are extensively covered in 21 parts, including the parts on conventional naval architecture and offshore engineering such as ship design and offshore decommissioning; the parts on ocean exploration such as underwater engineering, AUV/ROV, and polar engineering; the parts on harvesting of ocean resources such as deepwater mining and on utilizing the ocean space such as very large floating structures (VLFS) and aquaculture engineering; and the parts on sustainable ocean development such as offshore renewable energy, green shipping, and ocean environmental protection. This encyclopedia contains numerous illustrations and examples to make it easy to understand.

With the publication of this encyclopedia, *Ocean Engineering*, the editorial team wants to thank all those who have contributed to it. Please forgive us for not being able to name all the section editors here since they are specified in the next page, but we would like to convey sincere appreciations to our excellent section editors (SEs). You have done great work, and the time and effort spent

in organizing and reviewing entries is much appreciated. Besides, please let us acknowledge every author's contribution. We would not be able to begin without the help of all our brilliant authors. Finally, we are also very grateful to the Springer Nature supporting team. Thank you for always being there for this encyclopedia. The experience of working together in this 3-year project leaves an indelible impression on us.

Table of Contents

Alternative Fuel for Ship Propulsion	Concept Design
Analysis of Renewable Energy Devices	Concrete Platform
Application of Image Processing in Ice–Structure Interaction	Connectors of VLFS
Aquaculture Structures: Experimental Techniques	Cutting Technology of Steel
Aquaculture Structures: Numerical Methods	Damage Stability
Arctic Pipeline	Dead Ship Condition
Atmospheric Diving Suit (ADS)	Decommissioning of Fixed Platform
Autonomous Underwater Vehicle (AUV)	Decommissioning of Floating Platforms
AUV/ROV/HOV Control Systems	Decommissioning of Offshore Oil and Gas Installations
AUV/ROV/HOV Hydrostatics	Decommissioning of Subsea Facilities
AUV/ROV/HOV Propulsion System	Deep Sea Mining
AUV/ROV/HOV Resistance	Deep Submergence Rescue Vehicle (DSRV)
AUV/ROV/HOV Stability	Deep Tow System
Auxiliary Icebreaking Methods	Deep-Ocean Assessment and Reporting of Tsunamis (DART) BUOY
Beaching	Design of Mooring System
Bearing Capacity of Spudcans	Design of Pipelines and Risers
Big Data-Based Decision Support Systems	Design of Renewable Energy Devices
Biodiversity Conservation	Design of Submersibles
Block Assembly Line	Design Rules and Standards
Block Erection Technology	Design Spiral
Bucket Foundations	Detailed Design
Buffer Station	Diving of Anchors
Cable	Doppler Velocity Log for Navigation System in Underwater Vehicle
Capacity of Suction Anchor	Drag Anchors
Catenary Anchor Leg Mooring	Ductile-Brittle Transition of Sea Ice Under Uniaxial Compression and Its Engineering Applications
Catenary Mooring	Dynamic Analysis Method
Central Monitoring System	Dynamic Behavior and Fatigue
Christmas Tree	Dynamic Ice Loads and Structural Responses
Collector and Crusher	Dynamic Positioning in Ice
Complete and Partial Dismantling	
Compliant Tower Platform	
Computational Fluid Dynamics in AUV/ROV/HOV Hydrodynamics	

Economic Assessment	Hydroelasticity Theory
Empirical Design	Ice Breaking Vessel
Energy Efficiency Regulations from IMO	Ice Management in Offshore Operations
Environmental Impact Assessment System	Ice Tank Test
Environmental Perception for Underwater Vehicles	Iceberg Scouring
Eutrophication	Ice-Induced Vibration and Noise of Ships
Excessive Accelerations	Impact of Maritime Transport
Experimental Investigation of Offshore Renewable Energy	In Situ Permeability Measured Using Piezo-penetrometers
Experimental Techniques for VLFS	Installation and Decommissioning
Exploitation of Gas Hydrates	Installation of Offshore Pipelines
Explosive Removal	Installation of Spudcans
External Turret	Intact, Damage, and Dynamic Stability of Floating Structures
External Turret Single Point Mooring System	Integrated Navigation
Fatigue of Mooring Lines	Intelligent Control Algorithms in Underwater Vehicles
Fiber Optic Hydrophone	Internal Turret Single-Point Mooring (SPM) System
Fiber-Optic Cable	Introduction to Shipbuilding (Shipyard)
Field Development	Inventory of Hazardous Materials
Fishing Ships	Jacket Platform
Flexible Pipes and Umbilicals	Jack-Up Platforms
Flexural Strength of Sea Ice	Jellyfish Bloom
FLNG	Launching Technology
Floating Bridge	Lifting System
Fluid Effects During Iceberg-Structure Interactions	Local/Global Buckling and Propagation
Forming Technology of Profiles	Long Baseline Underwater Acoustic Location Technology
Forming Technology of Steel Hull Plates	Long-Term Storage
FPSO	Luxury Cruises
Future Trend on the Design, Building, and Operation of Ships for Energy Efficiency	Maneuverability of Polar Vessel
Glider	Marine Ecological Red Line
Global Buckling of Offshore Pipelines	Marine Operations
Global Navigation Satellite System (GNSS) Buoy	Marine Protected Areas in Areas Beyond National Jurisdiction
Green Tides	Mega-Float
Harmful Algal Blooms	Meteorological Monitoring and Measurement Buoy
Heave Plate	Microplastics
High-Performance Ship	Mineral Processing and Metallurgy
Homotopy Analysis Method	Modern Aquaculture Structures
Human Factors in Ship Design	Modification for Reuse
Human Factors in the Role of Energy Efficiency	Monopile Foundations in Offshore Wind Farm
Human Occupied Vehicle (HOV)	Moored Ship in Ice
Hybrid Remotely Operated Vehicle (HROV)/Autonomous and Remotely Operated Vehicle (ARV)	Mooring Anchor
Hydrodynamic Design	Mooring Connector
Hydrodynamics for Subsea Systems	

Mooring Lines	Profiling Float
Mooring System	Pure Loss of Stability
Mooring System of Renewable Energy Devices	Recycling Regulations
Multidisciplinary Design Optimization (MDO)	Reefing
Navigation Buoy	Reliability and Safety in Offshore Engineering
Navigation of Polar Vessel	Reliability-Based Design (RBD)
Net Structures: Biofouling and Antifouling	Remotely Operated Vehicle (ROV)
Net Structures: Design	Remotely Operated Vehicle (ROV) in Subsea Engineering
Net Structures: Hydrodynamics	Rescue Bell
New Technologies in Auxiliary Propulsions	Research Ship
Nonexplosive Removal	Resistance of Polar Vessel
Numerical Simulation Floe Ice–Sloping Structure Interactions	Resource Assessment
Numerical Simulation of Ice-Going Ships	Risk-Based Design for Ship and Offshore Structures
Numerical Tank	ROV Dynamic Positioning
Obstacle Avoidance Technology for Underwater Vehicle	Safety of Offshore Platforms
Ocean Thermal Energy Conversion	Salinity Gradient Power Conversion
Offshore In Situ Penetrometers	Second Generation Intact Stability Criteria
Offshore Pile Driving	Semi-submersible Platform
Offshore Structure Design Under Ice Loads	Semisubmersible Vehicle Autopilot Control System
Offshore Vessel	Service Ships
Offshore Wind Turbine-Ice Interactions	Shallow Foundations
Offshore Wind Turbines	Shear Strength
On-Bottom Stability of Submarine Pipelines	Ship Construction and Operation Impact on Energy Efficiency
Open Water Test	Ship Design Process
Optical Compass	Ship Electrical Design
Optimal Design	Ship Hull Lofting and Marking-Off
Painting Technology	Ship Machinery Design
Parametric Rolling	Ship Navigation System
Photoelectric Detection Technology in Underwater Vehicles	Ship Operational Environment
Physical Properties of Sea Ice	Ship Overall Design
Pile Capacity	Ship Propulsion System
Pipeline Soil Interactions	Ship Recycling
Piping Technology	Ship Recycling Facility Plan
Polar Acoustics	Ship Recycling Plan
Polar Communications	Ship Structural Design
Polar Materials	Ship-Fitting Design
Polar Merchant Vessel	Ship-Iceberg Interactions
Polar Offshore Engineering	Short Pile and Uplifting Capacity
Polar Propulsion	Simultaneous Localization and Mapping
Polar Research Vessel	Single Anchor Leg Mooring
Power Take-Off System	Single-Point Mooring
Power Transmission and Distribution	Size Effect and High-Pressure Zone of Sea Ice
Preliminary Design	Sloping Structure: Floe Ice Interactions
Probabilistic Aspects for Ice Loads on Ships	

Sloping Structure–Level Ice Interactions	Tidal and Ocean Current Turbines
Soft YOKE Single Point Mooring System	Towing Tank Test
Sonar Technology	Traditional Aquaculture Structures
SPAR Platform	Transport Ship
Spatial Variability	Tropical Atmosphere Ocean (TAO) Buoy
Special Marine Vehicle	Tsunami Warning Buoy
Spread Mooring System	Ultra-short Baseline Underwater Acoustic Location Technology
Static Analysis Method	Umbilical Cable
Station-Keeping System for VLFS	Underwater Acoustic Communication
Steel Pipelines and Risers	Underwater Acoustic Sensor Network
Steel Pretreatment	Underwater Driving Subsystem
Structural Analysis and Design of VLFS	Underwater Information Sensing Technology
Structural Characteristics of Polar Engineering	Underwater Lander
Structural Design	Underwater Mining System
Submarine	Underwater Welding
Submersible	Very Large Floating Structures (VLFS): Overview
Subsea Connector	Vortex Shedding and VIV Suppression
Subsea Equipment Installation Technology	Water Surface Support (Layout and Recovery) System
Subsea Hazards	Wave Energy Converters
Subsea Production System	Wave Energy Utilization Buoy
Suction Piles	Wave Measurement Buoy
Surface Buoy	Wave-Ice Interactions
Surface Mineral Storage and Dump	Welding Technology
Surface Warships	Winch
Surf-Riding and Broaching	Wind Tunnel Test
Taut Mooring	Winterization of Polar Engineering
Technical and Economical Barriers on Green Energy Utilization in Shipping	
Tension-Leg platform	
Thermal Insulation	
Thruster-Assisted Mooring	

About the Editors

Weicheng Cui

School of Engineering
Westlake University
Hangzhou, Zhejiang, China

Associate Editor, *Journal of Ship Mechanics*,
Shipbuilding of China

Editorial Board Member, *Marine Structures*,
Ocean Engineering, *Ships and Offshore Structures*,
Journal of Marine Science and Technology,
Journal of Engineering for the Maritime Environment,
Journal of Marine Science and Application,
Journal of marine science and engineering

Weicheng Cui joined Westlake University (WU) as a chair professor in September 2018, 1 month before its founding ceremony. The founding mission of WU is to become a global leader in frontier scientific research and a reformer in higher education in China. Dr. Cui's current research interests include (1) development of robotic fish-type submersibles and (2) fundamental research on the generalization of general system theory (GST) into theory of everything (TOE) for complex systems.

He got his B.Sc. from the Department of Engineering Mechanics at Tsinghua University in 1986 and his Ph.D. from the University of Bristol, England, in 1990. From 1990 to 1993, he did his postdoctoral research in the Department of Aerospace Engineering at the University of Bristol. He made some contributions in the aspects of measurement of interlaminar shear strength, nonlinear effect and size effect of the delamination strength, and the delamination mechanism for composite materials.

From February 1993 to May 1999, he worked at China Ship Scientific Research Center (CSSRC), and from June 1999 to September 2002, he was appointed as the Changjiang Professor at Shanghai Jiao Tong University. During these two periods, he mainly engaged in research in ship structural mechanics. He had made some contributions in the areas of the prediction of the ultimate strength of intact and damaged ship structures, fatigue strength assessment of ship structures, and reliability-based analysis and design of ship structures.

From October 2002 to March 2013, he worked at CSSRC again. Dr. Cui was the project leader and first deputy chief designer of Jiaolong deep manned submersible. He made some contributions in the application of multidisciplinary design optimization method and the establishment of a rational design standard for the manned cabin. Because of his outstanding contribution to the Jiaolong manned submersible development project, he won the Blancpain Hans Hass Fifty Fathoms Award, the First Prize in National Science and Technology Progress, and many honorary titles such as “The National Excellent Science and Technology Workers,” “The Deep Diving Hero” awarded by the Central Committee and the State Council, and the first batch of scholars of the National Innovation Talent Award.

From March 2013 to September 2018, he worked at Shanghai Ocean University, and from September 2018 onward, he has been working at Westlake University. He served as the project leader and chief designer of the Rainbowfish Challenging the Challenger Deep project from 2013 to 2020. In 2016, he was named one of “China’s Top Ten Science Stars” by *Nature*.

He is currently an editorial board member of six international journals, and the associate editor-in-chief of both *Shipbuilding of China* and the *Journal of Ship Mechanics*. He has published more than 400 papers in SCI and EI journals, being selected in Elsevier’s list of China’s Highly Cited Researchers continuously from 2017 to 2019.

**Shixiao Fu**

School of Naval Architecture, Ocean
and Civil Engineering
Shanghai Jiao Tong University
Shanghai, China

Associate Editor, *Marine Structures*, *Journal of Offshore Mechanics and Arctic Engineering*, *Proceeding of the Institute of Civil Engineers-Marine Engineering*

Editorial Board Member, *Journal of Hydrodynamics*, *China Ocean Engineering (in Chinese)*

Shixiao Fu got Bachelor and MSc degrees from DaLian University of Technology, and received his Ph.D. from Shanghai Jiao Tong University (SJTU) in 2005. In the next 2 years, he did his postdoctoral research at CeSOS, Norwegian University of Science and Technology (NTNU). He joined the faculty of Shanghai Jiao Tong University in 2008, served as a professor from 2009 to 2018, and was appointed as a distinguished professor in 2019.

Professor Fu has been selected as the Academician of the Norwegian Academy of Technological Sciences in 2020, and was granted China National Funds for Distinguished Young Scientists in 2018.

Professor Fu is now the vice director of the State Key Laboratory of Ocean Engineering at Shanghai Jiao Tong University, and the dean of the Research School of Polar and Deep Sea Technologies (joint research school between SJTU and Second Institute of Oceanography). He is also the associate editor of *Marine Structures* and the *Journal of Offshore Mechanics and Arctic Engineering*.

Professor Fu's research interests include hydroelasticity of floating bridges/tunnels and large-scale fish cage, vortex-induced vibration of flexible structures, experimental methods of force feedback control, and hybrid full-scale model testing.

**Zhiqiang Hu**

Marine, Offshore and Subsea Technology Group
School of Engineering
Newcastle University
Newcastle upon Tyne, UK

Associate Editor, *Ocean Engineering*

Zhiqiang Hu received his Ph.D. in naval architecture and ocean engineering from Shanghai Jiao Tong University in 2008 and had been working in Shanghai Jiao Tong University until 2016. He joined Newcastle University in 2016 and has been the Lloyds Professor of Offshore Engineering since 2018. Professor Hu has plenty of lecturing and research experience in offshore renewable energy, offshore hydrodynamics, structural dynamics, and basin experiment testing. Professor Hu has published approximately 100 scientific papers and currently is the deputy editor of the journal *Ocean Engineering*.

Definition

Alternative fuels for ship propulsion mean fuels which serve, at least partly, as a substitute for conventional fossil oil sources, normally heavy fuel oil (HFO), in the energy supply to shipping and which have the potential to contribute to its decarbonization and enhance the environmental performance of the shipping sector.

Driving Force for Alternative Fuels

Ships are a relatively fuel-efficient means of moving cargoes: for equivalent weights and distances, carbon dioxide emissions from shipping are considerably lower than air freight and road transport. At its best, emissions from shipping also undercut rail transport. This can be used as a rough proxy for transport costs and helps to illustrate the crucial role of international shipping in supporting global commerce, carrying as it does an estimated 90% of world trade. However, at the same time, the huge shipping quantity also makes shipping such a significant contributor to air pollution in terms of SO_x and NO_x emission, as well as

greenhouse gas emissions (accounting for 3% of global greenhouse gas emissions).

International Maritime Organization (IMO) and national environmental agencies have realized the impact of emission from shipping and therefore issued regulations and policies that drastically reduce emissions emanating from marine sources (IMO 2016; EU 2014, etc.). In particular, with the decision of IMO to limit the sulfur content of ship fuel from 1 January 2020 to 0.5% worldwide, more than 70,000 ships will be affected by the regulation. In addition, stricter limits on sulfur dioxide (SOx) emissions are already in place in Emission Control Areas (ECAs) in Europe and the Americas, and new control areas are being established in ports and coastal areas in China.

While these practical challenges related to sulfur reduction are knocking at the door, there is an accelerating worldwide trend toward pushing down CO₂ and nitrogen oxides (NOx) and particle emissions. In April 2018, IMO’s Marine Environment Protection Committee (MEPC), at its 72nd session, adopted an initial strategy on the reduction of greenhouse gas emissions from ships, setting out a vision to reduce GHG emissions from international shipping and phase them out, as soon as possible in this century. The vision confirms IMO’s commitment to reducing GHG emissions from international shipping, and, more specifically, under the identified “levels of ambition,” the initial strategy envisages for the first time a reduction in total GHG emissions from international shipping which, it says, should peak as soon

as possible and to reduce the total annual GHG emissions by at least 50% by 2050 compared to 2008 while, at the same time, pursuing efforts toward phasing them out entirely. The strategy includes a specific reference to “a pathway of CO₂ emissions reduction consistent with the Paris Agreement temperature goals.” The initial strategy represents a framework setting out the future vision for international shipping, the levels of ambition to reduce GHG emissions and guiding principles, and includes candidate short-, mid-, and long-term further measures with possible timelines and their impacts on States. A time map of actions from maritime authorities to promote greener shipping industry is presented in Fig. 1 (DNV GL 2019). The strategy also identifies barriers and supportive measures including capacity building, technical cooperation, and research and development (R&D).

Many ship operators, with present-day propulsion plants and marine fuels, cannot meet these new regulations without installing expensive exhaust after-treatment equipment or switching to more expensive marine fuels (such as MGO) or alternative fuels with properties that reduce engine emissions below mandated limits, all of which impact bottom-line profits (IMO 2016). The impact of these new national and international regulations on the shipping industries worldwide has brought alternative fuels to the forefront as a means for realizing compliance. The alternative fuels industry has grown dramatically for both liquid and gaseous fuels. In this context, the gradual adoption of alternative fuels

Alternative Fuel for Ship Propulsion, Fig. 1 Shipping becomes greener and more complex (Courtesy of DNV GL 2019)

by shipping would have a significant positive immediate environmental impact.

Basic Introduction to Alternative Fuels

There is a long list of alternative fuels that can be used in shipping. Among the proposed alternative fuels for shipping, LNG, methanol, hydrogen (particularly for use in fuel cells), and liquefied petroleum gas (LPG) are identified as the most promising solutions. All these fuels are virtually sulfur-free and can be used for compliance with sulfur content regulations, which is considered as the most urgent challenge for shipping. They can be used either in combination with conventional, oil-based marine fuels, thus covering only part of a vessel's energy demand, or to completely replace conventional fuels for some ships. The type of alternative fuel selected and the proportion of conventional fuel substituted will have a direct impact on the vessel's emissions, including GHG, NO_x, and SO_x.

Each of these alternative fuels has advantages and disadvantages from the standpoint of the shipping industry. One common challenge, however, posed by the adoption of most alternative fuels are their physicochemical characteristics, typically with associated low flashpoints, higher volatilities, different energy content per unit mass, and, in some cases, even toxicity. The adoption and entry into force of the draft International Code of Safety for Ships using gases or other low-flashpoint fuels (IGF Code), along with proposed amendments to make the code mandatory under SOLAS, by IMO Maritime Safety Committee 95 (MSC 95), on 11 June 2015, was a decisive step forward in addressing those challenges, at the regulatory level. The IGF Code includes mandatory provisions for the arrangement, installation, control, and monitoring of machinery, equipment, and systems using low-flashpoint fuels, such as liquefied natural gas (LNG), to minimize the risk to the ship, its crew, and the environment, having regard to the nature of the fuels involved. LNG has been the first focus of the IGF Code; however, provisions for methyl/ethyl alcohols, fuel cells, and low-flashpoint oil fuels are still being drafted as interim guidelines.

Key Applications

Liquefied Natural Gas (LNG)

LNG is a cryogenic fuel that is maintained at approximately -260°F (-162°C) at atmospheric pressure. The advantage of cooling and liquefying the fuel is that the volume is decreased approximately 600 times as compared to the gas. This advantage improves the energy density significantly for LNG. As a result, when compared to diesel fuel, LNG has about 2/3 as much energy on a volume basis and almost 90% as much energy on a weight basis. Natural gas consists primarily of methane, and typical composition is presented in Table 1 (Kolwzan and Narewski 2012).

The LNG fuel has a higher hydrogen-to-carbon ratio compared to oil-based fuels, which results in lower specific CO₂ emissions (kg of CO₂/kg of fuel). In addition, LNG is a clean fuel, containing no sulfur; this eliminates the SO_x emissions and almost eliminates the emissions of particulate matter. Additionally, the NO_x emissions are reduced by up to 90% due to reduced peak temperatures in the combustion process. Unfortunately, one of drawbacks of the use of LNG is the so-called methane slip during the valves overlap period for most four-stroke gas engines that is leading to the increase of the emissions of methane (CH₄), hence reducing the net global warming benefit from 25% to about 15%.

LNG as a liquid is not flammable or explosive. As any gas it has a flammability range. This range for LNG gas is between 5% and 15% when mixed with air. An explosion can only occur when the gas is in an enclosed space with air, the mixture is between 5 and 15%, and an ignition source is present. As with any flammable substance, proper design, regulations, and personnel training are needed to maintain a safe environment. Another major hazard for LNG as marine is that a spill of a cryogenic-like LNG

Alternative Fuel for Ship Propulsion, Table 1 Typical composition of natural gas in %

Methane	Ethane	Propane	Butane	Nitrogen
94	4.7	0.8	0.2	0.3

could result in structural damage of ships’ hull, deck, and other steel structures near the ship. Serious injuries could occur when LNG gets in contact with the human body.

An LNG fuel system onboard ships normally can be divided into four subsystems, namely,

LNG bunkering system, LNG storage system, fuel gas supply system (FGSS), and gas consumption installation system. Figure 2 shows the typical arrangement of low-pressure and high-pressure LNG fuel system onboard ships (McGill et al. 2013; DNV GL 2019).

Alternative Fuel for Ship Propulsion, Fig. 2 (a) Typical LNG fuel system (with low-pressure gas supply) onboard ships. (b) Typical LNG fuel system (with high-pressure gas supply) onboard ships

LNG is typically stored in highly insulated, spherical, or cylindrical tanks at low pressures (normally 1.05~5 bars). Fitting these tanks on a ship is quite feasible but requires some protection measures to reduce the risk of gas release due to collision with other ships or grounding. A detailed summary of various LNG fuel storage tanks is presented in Fig. 3.

Depending on the chosen gas engines, both high-pressure (HP) and low-pressure (LP) FGSS are available. For LP FGSS, LNG extracted from LNG fuel tank by pump or pressure build-up unit, and then vaporized and heated by glycol water, finally supplied to gas engines. For HP FGSS, LNG is firstly pressurized and then vaporized, which this is quite different from LNG carriers, because pressurizing liquid is much easier than gas.

Gas engines, gas turbines, and LNG storage and processing systems have been available for land installations for decades. LNG sea transport by LNG carrier also has a history going back to the middle of the last century. Developments to use LNG fuel in general shipping began early in the current century. Today, the technology required for using LNG as ship fuel is readily available. Piston engines and gas turbines, several LNG storage tank types, and process equipment are also commercially available.

Redundancy of fuel gas system shall be considered in particular for pure LNG-fueled ships; IGF Code stipulates that for single fuel installations, the fuel supply system shall be arranged with full redundancy and segregation all the way from the fuel tanks to the consumer, so that a leakage in one system does not lead to an unacceptable loss of power. In this regard, one pure gas engine with two fuel supply systems or two pure gas engines that each with one independent fuel supply system are both acceptable.

Conversion from diesel to LNG propulsion is possible, but the LNG is mainly relevant for newly constructed ships, since substantial modification of engines, the related piping, and allocation of extra storage capacity is required.

LNG presents hazards that are different than conventional marine fuels, like heavy fuel oil (HFO) and marine gas oil (MGO). If released at normal ambient temperatures and pressures, it will form a flammable vapor, so the release of LNG or natural gas should be prevented at all time. Furthermore, in its liquid phase, LNG is cold enough that it can cause ordinary steel to become brittle and crack, so any contact with steel structures and decks should be avoided. Because of these hazards and others that can occur, safety and the prevention of leakage need

Alternative Fuel for Ship Propulsion, Fig. 3 Different LNG fuel storage tank types according to IGF Code

to be among the primary objectives in the design, construction, and operation of LNG-fueled ships.

The three primary safety objectives for LNG fuel system onboard a ship are as follows:

- Prevent the occurrence of any hazardous release of gas or liquid.
- In the event of a release, prevent or contain any hazardous situations.
- If a hazardous incident does occur, limit the consequences and harmful effects.

A potential disadvantage to using LNG is space. Since gas weighs more, volume-wise it requires more space as compared to bunker oil. The farther the journey, the equally larger amount of storage space is required. So far, tanks are designed to be built in the cargo spaces of the ships for using gas as fuel. This is a major setback for the ship operators in terms of freight earned by the cargo. Engineers and architects are working toward developing systems that would make room for storing LNG. This could be anywhere on the vessel, above deck, in the superstructures, beneath the cargo containers, astern of the vessel, etc., and this would also call for extra insulation, piping, and steelwork as far as construction of the vessels is concerned.

LNG fuel surely holds a promising future in the shipping industry. However, only time can tell as to how well it becomes an integral part of the shipping industry in the days to come.

Methanol/Methyl Alcohol

Methanol, with the chemical structure CH_3OH , is the simplest alcohol with the lowest carbon content and highest hydrogen content of any liquid fuel. Methanol is a liquid between 176 and 338 K (-93 to $+65$ °C) at atmospheric pressure; it is a basic building block for hundreds of essential chemical commodities that contribute to our daily lives, such as building materials, plastic packaging, paints, and coatings. It is also a transport fuel and a hydrogen carrier for fuel cells (SSPA 2015).

Methanol can be produced from several different feedstock resources, mainly natural gas or

coal, but also from renewable resources like black liquor from pulp and paper mills, forest thinning or agricultural waste, and even directly from CO_2 that is captured from power plants. When produced from natural gas, a combination of steam reforming and partial oxidation is typically applied, with an energy efficiency up to about 70% (defined as energy stored in the methanol versus energy provided by natural gas). Renewable methanol is produced from pulp mill residue in Sweden, waste in Canada, and from CO_2 emissions at a small commercial plant in Iceland.

As an alternative liquid fuel, methanol is clean-burning, biodegradable, and sulfur-free. The only PM produced from burning methanol is from the pilot fuel (usually diesel). Methanol is able to meet the increasingly stringent emission reduction requirement such as the global sulfur limit of 0.5% by 2020 for the international shipping and acting as potential candidate to meet further greenhouse gas reduction targets. Major OEMs have shown methanol can meet Tier III NOx requirements with the aid of emulsification.

There are two main options for using methanol as fuel in conventional ship engines: in a two-stroke diesel-cycle engine or in a four-stroke, lean-burn Otto-cycle engine. Similar to LPG, only a single two-stroke diesel engine is currently commercially available, the MAN ME-LGI series, which is now in operation on methanol tankers. Wärtsilä four-stroke engines are in operation onboard the passenger ferry *Stena Germanica*. Another possibility would be to use methanol in fuel cells. A test installation has been running on the Viking Line ferry *MS Mariella* since 2017.

Methanol is a liquid fuel and can be stored in standard fuel tanks for liquid fuels, with certain modifications to accommodate its low-flashpoint properties and the requirements currently under development for the IGF Code at the IMO. Fuel tanks should be provided with an arrangement for safe inert gas purging and gas freeing.

Typical methanol fuel system onboard a ship can be divided into the following system elements:

- Bunkering of methanol
- Storage of methanol onboard

Hydrogen is an energy carrier and a widely used chemical commodity. It can be produced from various energy sources, such as by electrolysis of renewables or by reforming natural gas. Today, nearly all hydrogen is produced from natural gas.

For applications in the transport sector, production by reforming from natural gas is currently the most common method. If the resulting CO₂ would be captured, this could result in a zero-emission value chain for shipping.

When used in combination with marine fuel cells, the emissions associated with other marine fuels could be minimized or eliminated entirely. If H₂ is generated using renewable energy, nuclear power, or natural gas with carbon capture and storage, zero-emission ships are possible.

Power generation systems based on H₂ may eventually be an alternative to today's fossil-fuel-based systems. While fuel cells are considered the key technology for hydrogen, other applications are also under consideration, including gas turbines or internal combustion engines in stand-alone operation or in arrangements incorporating fuel cells. Hydrogen-fueled internal combustion engines for marine applications are said to be less efficient than diesel engines. Hydrogen-fueled piston engines for ships are not available in the market. On land development is ongoing. Possibly larger-scale industrial and maritime applications combined with waste heat recovery solutions might be better suited for high-temperature technologies such as solid oxide fuel cells (SOFC) or even industrial systems using molten carbonate fuel cells.

Fuel cells combined with batteries (and possibly super capacitors) adding peak-shaving effects are a promising option. Even proton-exchange membrane fuel cells (PEMFC), thanks to their flexible materials, could improve fuel cell lifetime significantly when protected against the harshest load gradients. SOFC must be applied in a hybrid environment using peak-shaving technology to be a realistic alternative for shipping.

Regarding the marine application, the European Commission FCSHIP study concluded in 2004 that the use of fuel cells in ships was feasible, with the usual caveats about availability and fuel supply. The subsequent METHAPU project sets out to

evaluate solid oxide fuel cell technology running on methanol for ship auxiliary power. For example, a 20 KW fuel cell system from Finnish company Wärtsilä was installed on the deck of the car carrier MV Undine. The 2009–2010 trial showed that the use of fuel cell technology and an alternative fuel poses no more of a risk to a commercial vessel than conventional equipment and fuel, laying the foundation for further deployment.

The FellowSHIP project has tested fuel cell technology integrated with a ship's propulsion system. In September 2009, a 330 KW molten carbonate fuel cell from MTU Onsite Energy was installed onboard the Viking Lady, an LNG-fueled ship with gas-electric propulsion system, without the need for pre-reforming. During the trial, the fuel cell logged 18,500 successful operating hours, providing supplementary power to the ship at an electrical efficiency of over 52% at full load. The next phase of FellowSHIP, now underway, is installing a battery pack for energy storage to create a true hybrid propulsion system for the Viking Lady.

Backed by the Norwegian Maritime Authority (NMA) and led by shipbuilder Fiskerstrand (see Fig. 5), the HYBRIDShips innovation project aims to have a pilot version of a hybrid hydrogen/battery-powered ferry operational by 2020. HYBRIDShips will establish the knowledge base necessary to build zero-emission propulsion systems for larger vessels and longer voyages. The pilot ferry will be the world's first such hybrid to combine hydrogen fuel cell power working alongside batteries.

In 2018 June, ABB and Ballard Power Systems decided to jointly develop zero-emission fuel cell power plant for shipping industry as in Fig. 6. The two companies propose to develop an electrical generating capacity of 3 MW (4000 horsepower) module and fit within a single module no bigger in size than a traditional marine engine running on fossil fuels.

Typically, a fuel cell power installation is shown as in Fig. 7. The IMO has looked at fuel cells as part of its Carriage of Cargoes and Containers Sub-Committee, with a view to include safety provisions in the International Code of Safety for Ships using gases or other low-flashpoint fuels (IGF) code.

Liquefied Petroleum Gas (LPG)

Liquefied petroleum gas (LPG) is any mixture of propane and butane in liquid form. In the USA, the term LPG is generally associated with propane. Specific mixtures of butane and propane are used to achieve desired saturation, pressure, and temperature characteristics. Propane is gaseous under ambient conditions, with a boiling point of -42°C . It can be handled as a liquid by

applying moderate pressure (8.4 bar at 20°C). Butane can be found in two forms: n-butane or isobutane, which have a boiling point of -0.5°C and -12°C , respectively. Since both isomers have higher boiling points than propane, they can be liquefied at lower pressure. Regarding land-based storage, propane tanks are equipped with safety valves to keep the pressure below 25 bar. LPG fuel tanks are larger than oil tanks due to the lower density of LPG.

COMPONENTS OF A TYPICAL FUEL CELL POWER INSTALLATION

Notes: 1) The boundaries show the groups of components as defined and do not reflect a spatial arrangement!
2) Subject to FC technology, not all components are applicable and configuration may vary.

Definitions: FUEL CELL POWER SYSTEM is the group of components which may contain fuel or hazardous vapors.

FUEL CELL SPACE(s) are defined as any space containing components of the group FUEL CELL POWER SYSTEM (but may contain additional components of the group FUEL CELL POWER INSTALLATION)

Alternative Fuel for Ship Propulsion, Fig. 7 Components of a typical fuel cell power installation

There are two main sources of LPG: it occurs as a by-product of oil and gas production or as a by-product of oil refinery. It is also possible to produce LPG from renewable sources, for example, as a by-product of renewable diesel production.

Basically, there are three main options for using LPG as ship fuel:

- In a two-stroke diesel-cycle engine
- In a four-stroke, lean-burn Otto-cycle engine
- In a gas turbine

Currently, only a single two-stroke diesel engine model is commercially available, the MAN ME-LGI series. In 2017, a Wartsila four-stroke engine was commissioned for stationary power generation (34SG series). This engine had to be derated to maintain a safe knock margin. An alternative technology offered by Wartsila consists in the installation of a gas reformer to turn

LPG and steam into methane by mixing them with CO₂ and hydrogen. This mixture can then be used in a regular gas or dual-fuel engine without derating.

LPG can be stored under pressure or refrigerated. It will not always be available in the temperature and pressure range a ship can handle. Therefore, the bunkering vessel and the ship to be bunkered must carry the necessary equipment and installations for safe bunkering. A pressurized LPG fuel tank is the preferred solution due to its simplicity and because the vessel can bunker more easily using either pressurized tanks or semi-refrigerated tanks without major modifications.

The cost of installing LPG systems onboard a vessel (e.g., internal combustion engine, fuel tanks, process system) is roughly half that of an LNG system if pressurized type C tanks are used in both cases. This is because there is no need for special materials that can handle cryogenic temperatures. On large ships, the cost difference

between LNG and LPG systems is lower if the LPG is stored in pressurized type C tanks, which are more expensive than large prismatic tanks. Alternatively, LPG can be stored at low temperatures in low-pressure tanks, which require thermal insulation.

Definition

Analysis refers to the application of scientific and engineering principles and processes to reveal the properties of a system.

Introduction

Renewable energy devices may operate in complex internal and external conditions, and engineering analysis is a key element of the design process. Because of the sophisticated physics associated with specific renewable energy devices, simplified analysis is often not adequate for a full understanding of the system behavior. With the advent of information and digital technologies, analysis at various fidelity levels can be achieved using simulation tools. To reduce the computational costs and to validate the accuracy of simulation tools, significant efforts have been invested from both industry and academia.

Analysis of Renewable Energy Devices,

Fig. 1 Schematic of a spar floating wind turbine and a jacket-supported offshore wind turbine

This chapter will focus on the analysis of renewable energy devices that operate in offshore environments. Such devices may experience hydrodynamic and aerodynamic load actions and have large dynamic motions and structural deformations. Figure 1 (left) presents an example of a floating wind turbine which is originally designed for the North Sea environments (Nielsen 2013). A bottom-fixed offshore wind turbine (OWT) is shown in Fig. 1 (right) which is intended for intermediate water depths below 50 m. At the design stage, dynamic response analysis must be performed to assess the power production quality, blade deflections in extreme wind conditions, platform pitch motions, mooring line dynamics, and so forth (Jiang et al. 2018).

Hydrostatic Analysis

Traditionally, hydrostatic analysis deals with naval architectures including ships and offshore

drilling units. To ensure safety of such floating installations, classification authorities (DNV GL 2013; ABS 2018) dictate that all offshore units have positive metacentric height in calm water position for afloat conditions and intact stability and damage stability be checked. Thus, hydrostatic analysis is also involved when renewable energy devices are supported on floating foundations. As shown in Fig. 2, a spar buoy has a simple geometry with a draft of T has hydrostatic pressure (p) acting on the submerged hull. The pressure is a function of the submerged depth. After a static heel within certain range, the buoy should be able to return to its equilibrium position with the assistance of the restoring moment created by the buoyancy and gravity forces. Details of hydrostatics can be found in Biran and Pulido (2013).

Note that hydrostatic analysis can be among the first steps in dimensioning the floating platforms. Luan et al. (2016) checked the intact stability of a semisubmersible wind turbine (Fig. 3) considering the overturning moment from

Analysis of Renewable Energy Devices,
Fig. 2 Schematic of a buoy and hydrostatic pressure

Analysis of Renewable Energy Devices,
Fig. 3 Illustration of the 5-MW CSC wind turbine (Luan et al. 2016)

aerodynamic loads and the righting moment by hydrostatic pressure. As shown in Fig. 4, the area under the righting moment curve (ϕ) is relatively large compared to the area under the design overturning moment (straight line), and large safety margin is indicated. Similar analyses can also be found in the works of Lefebvre and Collu (2012) and Karimirad and Michailides (2015).

Hydrodynamic Analysis

For renewable energy devices that are subjected to ocean waves and currents, hydrodynamic load can be an important source of excitation. Both viscous effects and potential flow effects (Faltinsen 1993) may play a role in determining the wave-induced loads and motions on certain types of renewable energy devices including wind turbines and wave energy converters. Figure 5 (upper) shows a vertical cylinder with diameter D that stands on the seabed, and an incident wave with wavelength of λ and wave height of H is propagating toward the cylinder. Based on Fig. 5 (lower), it is possible to judge which wave forces are of greater significance to the structure. If the cylinder is slender with large λ/D ratio, then viscous forces are prominent due to flow separation. For wind turbines supported by jacket or monopile foundations, the hydrodynamic forces acting on the foundations can often be represented by Morison's equation (ME); see Morison et al. (1950). Suppose that the slender structure can be divided into many strips, the hydrodynamic force per unit length normal to each strip can be expressed as

$$f_s = \rho C_M \frac{\pi D^2}{4} \ddot{x}_w - \rho (C_M - 1) \frac{\pi D^2}{4} \ddot{\eta}_1 + \frac{1}{2} \rho C_D D (\dot{x}_w - \dot{\eta}_1) |\dot{x}_w - \dot{\eta}_1| \quad (1)$$

where ρ is the density of seawater, D is the diameter of the slender structure, C_M is the mass coefficient, and C_D is the drag coefficient, $\dot{x}_w$ and $\ddot{x}_w$ are the velocity and acceleration of water particles at the strip center, and $\dot{\eta}_1$ and $\ddot{\eta}_1$ are the velocity and acceleration of the strip. In Eq. (1), C_M and C_D are dependent on the Reynolds number, the Keulegan-Carpenter number, and surface roughness. Reference values are given by offshore standards (NORSOK 2007; DNV 2010). As the strip velocity and acceleration are included in Eq. (1), this equation is also applicable to moving structures. Note that although the ME has been widely applied by industry and academia, this equation ignores lift forces, slamming forces, and axial Froude-Krylov forces.

A

Analysis of Renewable Energy Devices,
Fig. 5 Importance of mass, viscous, and diffraction forces on marine structures (Faltinsen 1993)

Hydrodynamic analysis of monopile-type wind turbines using the ME can be found in Veldkamp and Van Der Tempel (2005), Shirzadeh et al. (2013), and Jiang (2018). For monopile foundations supporting 10-megawatt (MW) wind turbines, the diameter can reach 10 m (Velarde 2016), and the ME is not necessarily applicable

for short waves. For jacket-type wind turbines, the tubular members have relatively small diameters. For example, the maximum leg diameters of traditional jackets supporting 5-MW wind turbines generally do not exceed 2 m (Chen et al. 2016; Dong et al. 2011). Thus, the hydrodynamic loads are drag-dominated for extreme waves, and the ME is well-suited for the analysis. Shi et al. (2013a, b) performed dynamic loads analysis of jacket-type wind turbines extensively and applied the ME during the hydrodynamic analysis. The ME has also been considered in the hydrodynamic analysis of floating platforms including spar buoy (Jonkman 2007; Jiang et al. 2013b), tension leg platform (Bachynski and Moan 2012), as well as mooring systems (Kvittem et al. 2012).

For floating renewable energy devices supported by large-volume structures, the diffraction effects are important, and potential flow theory is often used. Potential flow theory is realized numerically through the panel method (boundary element method), which solves the boundary-value problem for the interaction of wave-waves with prescribed motions in finite and infinite water depth (Lee 1995). Figure 6 schematizes a two-body wave energy converter which produces power using the relative heave motion between the torus and the float. A panel model is shown of the submerged parts. For a low-order panel method, the velocity potential is constant over the panel, and the diagonal length of the panel mesh is

Analysis of Renewable Energy Devices,

Fig. 6 Schematic of a two-body wave energy converter and the panel model (Muliawan et al. 2013a)

recommended to be below $1/6$ of the smallest wavelength analyzed (DNV 2010). Potential theory assumes ideal flow and ignores viscous effects. For floating structures with sharp corners, viscous effects may be more important, and Morison-type elements can be applied in time-domain simulations to complement the potential-flow solution. Kvittem et al. (2012) adopted this approach for a semisubmersible wind turbine with heave damping plates.

The panel method is a frequency-domain approach applicable to weakly nonlinear hydrodynamic problems. If there is highly nonlinear interaction between waves and floating bodies, analytical approaches (Faltinsen et al. 2004), the time-domain boundary element approaches (Schlør et al. 2016; Salehyar et al. 2017), or computational fluid dynamics methods (Li and Yu 2012) can be used. Chella et al. (2012) presented an overview of the wave impact forces on OWT substructures. Saletti (2018) studied the bottom slamming phenomenon for a combined wind and wave energy converter.

Additionally, a wave theory must be involved to calculate the wave kinematics which is closely correlated with the hydrodynamic loads. The linear wave theory, or the airy wave theory (Airy 1841; Craik 2004), is the simplest solution for the flow field and is only applicable for small-amplitude waves. Figure 7 shows the applicability

of various wave theories. Here, H denotes wave height, T is wave period, d is water depth, and L_0 is wavelength. Details on wave kinematics can be found in Dean and Dalrymple (1991).

Aerodynamic and Aeroelastic Analysis

For renewable energy devices that are exposed to wind loads, analysis of wind effect is indispensable. Wind turbines are particularly designed to harness the kinetic energy from the wind, and modern wind turbine blades are long and slender. For horizontal-axis wind turbines (HAWTs), the longest blade announced approaches 90 m for an 8-MW wind turbine (LM Wind Power 2018). Such flexible blades may experience large deformation under the combined effect of wind excitations, centrifugal forces, gravitational forces, and control actions. Aerodynamic analysis helps to understand the behavior of the airflow and the forces acting on the blades and the performance of the wind turbine. The classical blade element moment (BEM) was initially proposed by Glauert (1983) and modified for wind turbine analysis. The basic assumption of the BEM theory is that the force of a blade element is solely responsible for the change of axial momentum of the air which passes through the annulus swept by the elements, and there is no radial interaction between the

Analysis of Renewable Energy Devices,

Fig. 7 Applicability of wave theories (Sarpkaya 2010)

flows through contiguous annuli (Burton et al. 2011). BEM can be used to calculate the steady loads, the thrust, and the power of HAWTs. A simple BEM algorithm to find the axial and tangential induction factors is presented in Hansen (2008). A BEM algorithm with improved convergence rate is presented in Ning (2014). The classical BEM needs to be corrected by Prandtl's tip loss factor and Glauert correction to get reasonably good results, as compared to the measurements. Due to unsteadiness of the wind seen by the rotor, the classical BEM cannot realistically capture the aeroelastic behavior of wind turbines, and the unsteady BEM method should be considered. The unsteady BEM, albeit still efficient, considers the time behavior of loads and power by the dynamic wake model and the dynamic change of angle of attack by the dynamic stall model (Hansen 2008). Further, physical phenomena like wake meandering can also be incorporated as engineering corrections to BEM (Larsen et al. 2013).

The BEM theory considers uniform pressure distribution across a rotor plane. Unlike BEM, the generalized dynamic wake (GDW) method, also

known as the acceleration potential method, allows for a more general distribution of pressure across a rotor plane and includes inherent modeling of the dynamic wake effect, tip losses, and skewed wake aerodynamics (Moriarty and Hansen 2005). However, the GDW method was developed for lightly loaded rotors at high wind speeds, and the induced velocities are small relative to the mean inflow velocity. Detailed descriptions of the GDW theory can be found in Pitt and Peters (1980) and Suzuki (2000).

Over the past decades, computational fluid dynamics (CFD) has been widely used in aerodynamic analysis of rotors, and actuator disc and actuator line methods are special types of CFD methods (Hansen and Aagaard Madsen 2011). Krogstad and Eriksen (2013) presented a summary of different computational methods that were applied to predict the performance and wake development of a tested model wind turbine. De Vaal et al. (2014) used the actuator disc model to study the effect of surge motion of a floating wind turbine on rotor thrust and induced velocity. Wen et al. (2018) applied the free vortex method to study the power coefficient

overshoot of a floating wind turbine in surge oscillations.

Aeroelastic analysis refers to the type of analysis that deals with the interaction between the inertial, elastic, and aerodynamic forces when the structure is exposed to a fluid flow. For commercial wind turbines, stall-induced vibrations and classical flutter are two categories of instabilities that have been observed for stall- and pitch-regulated wind turbines, respectively. Hansen (2003, 2007) presented a state-of-the-art review on aeroelastic stability analysis of wind turbines.

Integrated Dynamic Analysis

A complex renewable energy system may comprise structural components, mechanical parts, electrical devices, and control systems. Modeling and simulation of such systems can be achieved by using numerical methods such as multibody simulation (MBS) or finite element method (FEM). Integrated dynamic analysis of renewable energy devices under external load conditions is usually performed in the time domain and

provides global and structural responses. For OWTs, the integrated dynamic analysis is also addressed as aero-hydro-servo-elastic analysis (Jonkman et al. 2008) as aerodynamics, hydrodynamics, servo dynamics, and structural dynamics are involved in the analysis. Figure 8 illustrates the computational flowchart of an integrated dynamic analysis in the HAWC2 program (Larsen 2009). As shown, user-specified control actions including mechanical system faults can be added to the main program via external dynamic-link libraries (DLLs) written in a programming language. For HAWTs, blade pitch control and generator torque control are also achieved through DLLs. There exist many engineering challenges with regard to modeling complexity, coupling of different submodules, nonlinear responses, and time-domain efficiency; see Butterfield et al. (2007).

Global motions and structural responses are two main aspects of concern. The global motions refer to the horizontal displacement and rotation of structural members or bodies. For floating wind turbines, rigid body motions of the floating platforms under dynamic loading can provide insights

Analysis of Renewable Energy Devices,

Fig. 8 Modularized computational flowchart for floating wind turbine simulation (Jiang et al. 2013a)

into system dynamics. Nielsen et al. (2006) conducted dynamic response analysis of the floating wind turbine concept HYWIND under wind, wave, and current conditions and compared the simulated and experimental decay tests of tower pitch angle. Pereya et al. (2018) analyzed the nacelle acceleration and platform pitch motion of the TetraSpar floating wind turbine. Such global motion responses, albeit not stated explicitly, can form design constraints for drivetrain components. Kurniawan et al. (2012) performed modeling and global motion analysis of a pitching wave energy converter and discussed dynamics of such a system with different hydraulic components. Muliawan et al. (2013b) conducted dynamic response analysis of a combined wind-wave energy converter and uncovered positive synergy between the two floating bodies by global motion analysis. Shi et al. (2016) developed an ice load force module for an aero-hydro-servo-elastic program and identified important response characteristics of a monopile-type wind turbine under combined ice and wave loads. From an integrated dynamic analysis, structural responses are available. To ensure structural integrity of renewable energy devices, the structural responses need be checked against possible failure modes including fatigue and ultimate limit states. Dong et al. (2011) checked the long-term fatigue damage of tubular joints of a jacket-type OWT (see Fig. 1 right) after performing integrated dynamic

analysis. Jiang et al. (2015) analyzed the short-term fatigue damage of mooring lines of a floating wind turbine during shutdown. Wei et al. (2014) calculated the structural capacity of jacket support structure of an OWT under extreme wind and wave loading.

Analysis of Mechanical Components

For many renewable energy devices, mechanical components are widely used to transfer the energy to the generator side. Figure 9 demonstrates a three-stage gearbox of a 750-kilowatt stall-regulated wind turbine. The gearbox has one planetary stage and two parallel stages. High failure rates of gearbox components have been observed for the wind industry since its inception (McNiff et al. 1991), and analysis of mechanical components sometimes requires knowledge of both external loading conditions from the rotor side and internal conditions like friction, oil viscosity, and lubricant temperature (Harris and Kotzalas 2007). Numerical methods like FEM and MBS are useful tools for modeling the detailed setup of mechanical components and to study the internal responses under dynamic conditions. Using FEM and MBS, Xing and Moan (2013) showed that the main shaft non-torque loads can substantially contribute to the bearing loads and gear displacements. Dong et al. (2012) investigated gear

Analysis of Renewable Energy Devices,

Fig. 9 Illustration of a wind turbine gearbox (Image source: (Jiang et al. 2014a), courtesy of National Renewable Energy Laboratory)

contact fatigue in a wind turbine drivetrain using a decoupled analysis approach. Jiang et al. (2014a) proposed using multilevel integrated analysis for contact fatigue analysis of planetary bearings. Nejad et al. (2014, 2016) analyzed dynamic load effects of a drivetrain components and performed reliability analysis of wind turbine gears.

Hydraulic components including valves, pumps, accumulators, pipelines, and motors are also mechanical components that have been suggested for use in wave energy converters and wind turbines. Analysis of hydraulic systems often involves mathematical modeling and numerical simulations. Henderson (2006) presented both numerical simulation and laboratory tests of the hydraulic system employed in the Pelamis wave energy converter. Yang et al. (2010) investigated the wear damage in the piston ring and cylinder bore of a heaving-buoy wave energy converter. Numerical simulations of hydraulic transmission of wind turbines can be found in the works of Jiang et al. (2014b), Yang et al. (2015), Buhagiar et al. (2016), and Buhagiar and Sant (2017).

Code Verification and Validation

A multitude of design codes have been developed and extensively used for analysis of renewable energy devices. In general, many design codes adopt simplified physical representations of actual systems with reduced degrees of freedom but account for most prominent system features. Before being put into use, a new code should be verified against other state-of-the-art codes with adequate model fidelity levels or validated against experimental results. Larsen et al. (2013) showed good comparison between HAWC2 and the CFD code EllipSys3D for aerodynamic forces on a blade. Extensive benchmark work usually involves international collaboration among various academic and industrial partners. Passon et al. (2007) introduced the first international investigation and verification of aeroelastic codes for OWTs. Modeling capabilities of offshore environment, structural modeling, and rotor aerodynamics were compared among nine design codes for

four different support structures. Later, code-to-code verifications were conducted of other types of foundations with an increased number of participants and additional load cases; see Jonkman et al. (2008), Popko et al. (2012), and Vorpahl et al. (2014).

Experiments at model scale or full-scale testing are other effective means of code verification. Discrepancies in results between model testing and numerical codes are not uncommon, especially for renewable energy devices that have both aerodynamic and hydrodynamic excitations, because similarity between inertia and viscous forces of the models cannot be achieved simultaneously. Li and Calisal (2010) developed numerical codes using a discrete vortex method for vertical axis tidal current turbines and verified the two- and three-dimensional codes with experiments. Preliminary verification of a wave energy converter design tool with experimental wave tank results is presented in Ruehl et al. (2014). Coulling et al. (2013) verified a numerical model constructed in the design code FAST (Jonkman and Buhl 2005) with 1/50th-scale model test data for a semisubmersible floating wind turbine system. Luan et al. (2018) compared the simulated sectional responses of a semisubmersible using a nonlinear finite element code SIMO-Riflex with the 1/30th-scale model test results.

Application of Image Processing in Ice–Structure Interaction

Qin Zhang
Department of Marine Technology, Norwegian University of Science and Technology, Trondheim, Norway

Introduction

The understanding of Arctic physical processes and sustainable exploration, exploitation, and management of Arctic resources require more

detailed, precise, and continuous measurements of sea ice parameters. Because various types of ice are in the ice-covered regions and the sizes of the ice floes can range from about 1 meter to kilometers, the temporally and spatially continuous field observations of sea ice are necessary for marine activities. One of the best ways of observing the ice conditions in the oceans is by using aerial or nautical imagery. The use of cameras as sensors on mobile sensor platforms (e.g., unmanned vehicles) will aid the development of sea ice observation. It has the potential of continuous measurements with high precision, which is particularly important for providing detailed localized information of sea ice to ensure safe operations of structures in ice-covered regions (Haugen et al. 2011).

The collected ice images or videos must be analyzed by dedicated computer algorithms to extract useful ice information to dynamic ice estimators and for decision support in Arctic offshore engineering. Therefore, this article introduces image processing algorithms for providing the ice parameters that are important factors in the analysis of ice–structure interaction in an ice field. These useful ice parameters include ice concentration, ice types, ice floe size, and floe size distribution, and they are defined as follows.

Ice Concentration

Ice concentration (IC) is the ratio of ice on unit area of sea surface; it has been identified as one of the most influencing parameters on the magnitude of experienced forces during model tests (van der Werff et al. 2012; Comfort et al. 1999). To obtain ice concentration from a visual ice image, only the visible ice can be considered, including brash ice, and submerged ice if visible in the image. With the image area, the height of image taken above the ice sheet, and the segmentation which is the identification of the ice from water, the actual area of sea ice and sea surface can be derived. However, the actual domain area is not necessary for calculating ice concentration. In simplified terms, ice concentration from a digital visual image is defined as the area of sea surface covered by visible ice observable in the 2D visual image taken vertically from above, as a fraction of the

whole sea surface domain area. Hence, it is the ratio of the number of pixels of visible ice to the total number of pixels within the image domain. Note that the domain area is an effective area within the image, excluding land or other nonrelevant areas. The ice concentration is then given by (Zhang et al. 2012a)

$$\begin{aligned}
 IC &= f(\text{image area, height above ice sheet, segmentation}) \\
 &= \frac{\text{Area of all visible ice}}{\text{Actual domain area}} \\
 &= \frac{\text{No. of pixels of visible ice in image domain}}{\text{Total no. of pixels in image domain}}
 \end{aligned} \tag{1}$$

Ice Types

Sea ice is any form of ice found at sea which has originated from the freezing of sea water. Different types of sea ice have different physical properties. Since one generally assumes that brash ice has a dampening effect in models for calculating ice pressure and ice forces, it may be more convenient to estimate the distribution between three classes, that is, the ratio of ice floes, the ratio of brash ice, and the ratio of water. As defined (Løset et al. 2006):

- Floe is any relatively flat piece of sea ice 20 m or more across. It is subdivided according to horizontal extent. A giant floe is over 10 km across; a vast floe is 2–10 km across; a big floe is 500–2000 m across; a medium floe is 100–500 m across; and a small floe is 20–100 m across.
- Ice cake is any relatively flat piece of sea ice less than 20 m across.
- Brash ice is accumulations of floating ice made up of fragments not more than 2 m across and the wreckage of other forms of ice. It is common between colliding floes or in regions where pressure ridges have collapsed.
- Slush is snow which is saturated and mixed with water on land or ice surfaces or as a viscous floating mass in water after heavy snowfall.

For simplicity, the size of sea ice piece is the only criterion to distinguish ice floe and brash ice

in this research. That is, any relatively flat piece of sea ice 2 m or more across is considered as “ice floe,” while any relatively flat piece of sea ice less than 2 m across is considered as “brash ice (piece).” And the rest of ice pixels, e.g., single ice pixels or the ice pieces that are too small to be treated as brash ice, are considered as “slush.”

Ice Floe Size and Floe Size Distribution

The estimation of ice floe size and floe size distribution among the “ice floes” gives an important set of parameters from ice images. In image processing, the ice floe size can be determined by the number of pixels in the identified floe. If the focal length f and camera height are available, the actual size in SI unit of the ice floes and floe size distribution can also be calculated (Lu and Li 2010) by converting the image pixel size to its SI unit size.

Image Processing Methods

A digital image is a numeric representation of a two-dimensional picture, and it is composed of pixels which are the smallest individual elements in the image. A pixel holds quantized values that represent the color or gray level of the image at a particular point.

Ice Pixel Detection

Ice concentration, as defined, is a binary decision of each pixel to determine whether it belongs to the class “ice” or to the class “water.” From Eq. 1, it is clear that the detection of the ice pixels from water pixels is crucial to obtaining the ice concentration from an ice image.

Otsu Thresholding

The pixels in the same region have similar intensity. Based on that sea ice is whiter than open water, ice pixels have higher intensity values than those belonging to water in a uniform illumination ice image. Thus, the thresholding, which is based on the pixel’s gray-level to turn a grayscale image into a binary image (whose pixels have only two possible intensity values, e.g., “0” and “1”), is a natural way to segment ice regions from water regions.

Assuming that an object is brighter than the background, the object and background pixels have intensity levels grouped into two dominant modes. A threshold value T is chosen to separate an image into an “object region” and a “background region.” Individual pixels are marked as “object” pixels if their value is greater than the threshold value and as “background” pixels otherwise, that is:

$$g(x, y) = \begin{cases} 1 & \text{if } f(x, y) > T \\ 0 & \text{if } f(x, y) \leq T \end{cases} \quad (2)$$

where $g(x, y)$ and $f(x, y)$ are the pixel values located in the x^{th} column and y^{th} row of the binary and grayscale image, respectively. Then, the grayscale image is turned into a binary image. The key of thresholding method is how to select the threshold value.

The Otsu thresholding method (Otsu 1975) is one of the most common automatic threshold segmentation algorithms. It requires that the histogram (the distribution of gray value) is bimodal and the illumination is uniform. In this method, the histogram of the image is divided into two classes (i.e., the pixels are classified as either foreground or background), and the goal is to find the threshold value that minimizes the within-class variance, given by (Otsu 1975)

$$\sigma_w^2(T) = \omega_1(T)\sigma_1^2(T) + \omega_2(T)\sigma_2^2(T) \quad (3)$$

where ω_1 and ω_2 are the probabilities of the two classes separated by a threshold T and σ_1 and σ_2 are the variances of these two classes. The threshold with the maximum between-class variance also has the minimum within-class variance. The between-class variance is given by (Otsu 1975)

$$\begin{aligned} \sigma_b^2(T) &= \omega_1(T)(\mu_1(T) - \mu(T))^2 + \omega_2(T)(\mu_2(T) - \mu(T))^2 \\ &\cong \omega_1(T)\omega_2(T)(\mu_1(T) - \mu_2(T))^2 \end{aligned} \quad (4)$$

where μ_1 and μ_2 are the means of these two classes and $\mu(T) = \omega_1(T)\mu_1(T) + \omega_2(T)\mu_2(T)$. This expression can also be used to find the best threshold and to update the threshold value iteratively.

K-means Clustering

Clustering is a statistical data analysis method that divides a data set into many groups (Basak et al. 1988), and it has been widely used in image segmentation, especially classifying the objects into many groups. This method is based on the mathematical distance measure between individual observations and groups of observations to find hidden structures in unlabeled data and assign the unlabeled data into groups, so that the data in one group are more similar to each other than to those in other groups.

Among various clustering algorithms, *k*-means is one of the simplest but most popular clustering algorithms. The goal of *k*-means clustering is to minimize the within-cluster sum of distance to partition a set of data into *k* clusters (MacQueen 1967). The step-by-step algorithm for this method in image segmentation is described below:

Step 1:

For image processing, a set of gray levels is given:

$$f(x_1, y_1), f(x_2, y_2), \dots, f(x_n, y_n). \quad (5)$$

Step 2:

Partition this set into *k* clusters:

$$\begin{aligned} f_i(x_1, y_1), f_i(x_2, y_2), \dots, f_i(x_{n_i}, y_{n_i}) & \quad i \\ = 1, 2, \dots, k. \end{aligned} \quad (6)$$

Step 3:

Calculate the local means of each cluster:

$$c_i = \frac{1}{n_i} \sum_{m=1}^{n_i} f_i(x_m, y_m) \quad i = 1, 2, \dots, k. \quad (7)$$

Step 4:

Gray level $f(x_j, y_j)$ ($j = 1, 2, \dots, n$) belongs to set p ($p = 1, 2, \dots, k$) if it has the shortest distance to set p than any other sets:

$$\begin{aligned} |f(x_j, y_j) - c_p| & \leq |f(x_j, y_j) - c_i| \quad i \\ & = 1, 2, \dots, k. \end{aligned} \quad (8)$$

Iterate Steps 3 and 4 until the local means are unchanged.

Ice Floe Boundary Detection

In image processing, the detection of ice floe boundaries can be used to distinguish individual ice floes. With the individual ice floe identification result, ice floe characteristics, such as location, area, perimeter, and shape measurements of each ice floe, together with the floe size distribution can thereby be estimated. Thus, ice floe boundary detection is a vital for extracting information of ice floes from ice images.

In an actual ice-covered environment, especially in marginal ice zone (MIZ), ice floes typically touch each other, and the edges between touching floes may be difficult to identify in digital images. This issue significantly affects the analysis of individual ice floe properties and floe size distribution. Among various floe boundary detection methods, for example, derivative boundary detection (Zhang et al. 2012a, b), morphology-based method (Zhang et al. 2012a, b; Banfield 1991; Banfield and Raftery 1992), watershed-based algorithms (Blunt et al. 2012; Zhang et al. 2013), etc., the GVF (gradient vector flow) snake-based approach (Zhang et al. 2015; Zhang and Skjetne 2015) is the most advanced method nowadays.

The GVF snake algorithm (Xu and Prince 1998) is an extension of the traditional snake (also known as active contours) algorithm (Kass et al. 1988) (the details of the traditional and GVF snake algorithms can be found in “Appendix A”). It has a good capability in the detection of weak boundaries. However, proper initial contours (an initial contour is a starting set of snake points for the evolution) are required by the GVF snake algorithm in ice floe boundary detection, especially when detecting the boundaries of massive ice floes. For each ice floe, it was showed that the initial contour close to the actual floe boundary, located inside the floe and centered as close to the ice floe center, is most effective (Zhang and Skjetne 2015). To accomplish the requirements of the initial contour without manual interaction, an automatic contour initialization algorithm based on the distance transform (the details of the distance transform can be found in “Appendix B”) and its regional maxima (a regional maximum is a connected component of pixels with a value

Application of Image Processing in Ice–Structure Interaction,
Fig. 1 Contour initialization algorithm

(a) Binary image matrix.

(b) Distance transform of Fig. 1(a), regional maximum, seed, and initial contour.

greater than any of its neighbors) is concluded as follows (Zhang and Skjetne 2014, 2015):

Step 1:

Convert the ice image into binary image after separating the ice from the water, in which case the pixels with value “1” indicate ice and pixels with value “0” indicate water; see Fig. 1a.

Step 2:

Perform the distance transform to the binary image, and find the regional maxima shown as the green numerals in Fig. 1b.

Step 3:

Merge the regional maxima into a big one if they have a short distance to each other, and then find the “seeds” that are centers of the regional maxima (including the merged ones), shown as red “+” in Figs. 1b and 2b.

Step 4:

Initialize the circular-shaped contours located at the seeds with the radii selected according to the pixel value at the seeds in the distance map; see the blue circles in Figs. 1b and 2b.

After initializing the contours, the GVF snake algorithm is run on each contour to detect the floe boundary. By superimposing all the detected boundaries over the binarized ice image, it allows to separate touching ice floes and thereby be able to identify individual floes, as shown in Fig. 2.

Floe Shape Enhancement

Some segmented floes may contain holes or smaller ice floes inside after boundary detection, and the shape of the segmented ice floe is rough. To smoothen the shape of the ice floe, morphological cleaning is used after ice floe boundary detection.

Morphological cleaning is a combination of first morphological closing and then morphological opening (Soh et al. 1998) on an image. Assume A is a binary image and B is a chosen structuring element (a structuring element is a shape that is used to probe an input image and draw conclusions on how the structuring element fits or misses the shapes in the input image. It can be represented as a matrix of 1 s, indicating the points that belong to the structuring element, and 0 s indicating otherwise); the morphological closing of A by B , denoted $A \bullet B$, is a dilation followed by an erosion (the details of dilation and erosion operations can be found in “Appendix C”):

$$A \bullet B = (A \oplus B) \ominus B \quad (9)$$

where $\oplus$ and $\ominus$ denote dilation and erosion, respectively. The morphological closing is the complement of the union of all translations of B that do not overlap A . It tends to smooth the contours of objects, generally joins narrow breaks, fills long thin gulfs, and fills holes smaller than the structuring element as seen in Fig. 3b.

(a) Sea ice floe image.

(b) Binary image with initial contours.

(c) separation result, individual floes are labeled in different colors.

[illegible][illegible][illegible]

To ensure that smaller ice floes contained in larger floes are removed, the morphological cleaning should be performed on smaller floes

Application of Image Processing in Ice–Structure Interaction, Fig. 4 Ice shape enhancement

Application of Image Processing in Ice–Structure Interaction, Table 1 Managed ice conditions in the test runs, target values (full scale)

Run no.	IC [%]	Floe size 1 (45%) [m]	Floe size 2 (40%) [m]	Floe size 3 (15%) [m]
5100	86	0.50	1.00	1.50
5200	70	0.50	1.00	1.50
5300	70	0.25	0.50	0.75
5400	86	0.25	0.50	0.75

first. Thus, the shape enhancement includes following two steps (Zhang and Skjetne 2014):

Step 1:

Arrange all the segmented ice floes from small to large.

Step 2:

Perform the morphological cleaning to the arranged ice floes in sequence.

The shape enhancement result is shown in Fig. 4c.

Applications in Arctic Offshore Engineering

Model Ice Image Processing Applications

Before performing an analysis at full scale, the dynamic positioning (DP) experiments in model ice at the Hamburg Ship Model Basin (HSVA) in May 2011 allow for the testing of relevant image processing algorithms. This section shows the applications of the image processing techniques for determining important ice parameters from model ice data in the model-scale ice–structure analysis.

In these DP experiments, a managed ice condition was obtained by cutting the level ice layer into predefined ice floe shapes, and the behavior of two different model ships (an Arctic drillship and a polar research vessel) in a broken-ice field was studied. Four different types of ice fields were tested, varying in ice concentration and ice floe size distribution, as shown in Table 1. The model ice image data provided from the experiments includes two complete overview pictures from run nos. 5100 and 5200 and the videos of each of the four model test runs (see Table 1). The overall tank images were retrieved by stitching 28 top view pictures taken before execution of the model tests, showing a complete overview of the ice floe distribution in the ice tank, as seen in Fig. 5. The videos captured the local conditions around the fixed model vessel with a constant heading of 180° during each run by a top view video camera moving along with the carriage and model, as seen in Fig. 6. The four model ice videos are more than 24 min long with a frame rate of 25 fps. Since a video is composed from a sequence of frames, by gathering the result for each analyzed frame, the model ice parameters over time are retrieved. Before applying the algorithms to these videos, one frame per second is

Application of Image Processing in Ice-Structure Interaction, Fig. 5 Overall tank image for run no. 5100. Target ice concentration of 86%

Application of Image Processing in Ice-Structure Interaction, Fig. 6 One frame in the original video. Run no. 5400

found sufficient, and each frame was fed to the program for further processing (Zhang et al. 2012b).

Ice Concentration

Both Otsu thresholding and k -means clustering methods have been used to determine the ice concentration in model basin for run nos. 5100 and 5200. The analysis results are compared with the target ice concentration values, as presented in Table 2. Because the intensity values of all the model ice pixels are significantly higher than water pixels, both methods give similar result (Zhang et al. 2012b) and are both effective, as shown in Fig. 7.

When analyzing the ice concentrations in the vicinity of the model ship, the impediments around the tank in the videos are removed, and the vessel in the middle bottom of the tank is eliminated by a black rectangle, as seen in Fig. 8a. Then, the Otsu's and the k -means

Application of Image Processing in Ice-Structure Interaction, Table 2 Ice concentrations derived from different methods

Methods	Target value (%)	Otsu (%)	K-means (%)
Run no. 5100	86	83.17	82.86
Run no. 5200	70	62.50	62.00

methods are applied in the video processing to calculate the ice concentration as a function of time. Figure 9 shows the variation of the calculated ice concentration in time for all test runs based on the Otsu's method, and the average ice concentrations after reaching the limiting values in all test runs are summarized in Table 3. Reduced ice concentration in the initial part of the test runs (before convergence) is related to the model ship positioning. It is an unwanted phenomenon, since it reduces the effective length of the ice tank. In all test runs, it was observed that the ice concentration in the near vicinity of the model was reaching a limiting value of approximately 80–89%, irrespective of the starting ice concentrations and floe sizes. This phenomenon can be explained by the tank's wall effect. That is, the ice floes were compacted by the model ship toward the end of the basin, such that the ice concentration asymptotically approached a limiting value.

Within the image analysis results, the time series of the ice concentration have been compared with the absolute total hull forces that were measured during the tests to investigate the relation between the ice concentration and the hull forces (see Fig. 10, for instance) (van der Werff et al. 2012). Further investigations are under consideration.

Model Ice Floe Monitoring

In one of the model ice tests as seen in Fig. 11a, the ice floes were modeled square shapes with predefined side lengths, and the largest floe has an area less than a predefined value. To evolve the GVF snake algorithm effectively for identifying ice floe boundaries, an automatic initial contour initialization method was introduced in section “Ice Floe Boundary Detection.”. However, it is difficult for the contour initialization method to initialize the contours for each square-shaped ice floe as shown in Fig. 11b, so that the GVF snake algorithm is unable to find all floe boundaries and many floes still touch each other as shown in Fig. 11c. Thus, an additional round of contour initialization and segmentation is required.

In this model ice test, although these model ice floes are not perfect squares, most of the floes could be approximated as rectangles with a length-to-width ratio less than the given threshold. Based on the characteristics of these rectangle-shaped model ice floes, the following three criteria can be used to determine whether it is necessary to initialize the contours and conduct a second segmentation (Zhang et al. 2015):

- The ice floe area is less than a given threshold.
- The ice floe has a convex shape (it could be done by determining if the ratio between the floe area and its minimum bounding polygon area is larger than the threshold).

(a) Model ice image with crowded floes.

(b) Initializing the contours once.

(c) Results after first round.

(d) Initializing the contours twice.

(e) Final result.

- The length-to-width ratio of the minimum bounding rectangle of the ice floe is less than the threshold.

Note that these criteria are designed for segmenting the rectangular-shaped crowded model ice floes only. For crowded model ice floes with other shapes, the criteria can be replaced by the corresponding shape criteria.

After a segmentation step, the algorithm will stop if all the segmented floes satisfy these criteria. Otherwise, the algorithm must find the floes that do not satisfy any of these criteria, find their seeds, initialize new contours, and perform the segmentation again (e.g., seen in Fig. 11d, e). After several segmentation steps, some segmented floes may still not satisfy the criteria. This is mainly because the boundaries of those floes are too weak to be detected. However, the total number of segmented floes will converge to a final solution. Therefore, the algorithm is made to stop if the total number of floes segmented after steps N and $N + 1$ are equal, in combination with an absolute stop criterion.

Finally, the ice shape enhancement algorithm is performed on the overall segmented model ice floe image to obtain the final model ice floe identification result. Figure 12 presents an example showing the crowded model ice floe identification result from Fig. 5 and the corresponding floe size distribution of an overall ice tank image (Zhang et al. 2015).

This model ice floe identification algorithm has been applied to an ice surveillance video to monitor the maximum floe size entering the protected vessel from a physical ice management operation, as seen in Fig. 13b. The maximum floe size for each frame is calculated as a function of time as seen in Fig. 14. Based on this result, a warning can be sent to the risk management system if the estimated risk based on the maximum floe size is too large.

Sea Ice Image Processing Applications

The Norwegian University of Science and Technology (NTNU) expedition Oden Arctic Technology Research Cruise 2015 (OATRC'15) was

(a) Ice floe identification. The floe positions, found by averaging the positions of the pixels of each floe, are denoted using black dots.

(b) Floe size distribution histogram.

(a) Pre-processed frame at 965s.

(b) Segmentation result of (a).

carried out in the Arctic region in September 2015. During the research cruise, one of the helicopter flight missions was to capture ice conditions in the marginal ice zone (MIZ). The images contain valuable ice information in the MIZ. In this section, several methods are sequentially presented with an example to demonstrate an automated procedure for ice floe and brash ice identification, their numerical representation, and forthcoming ice field generation.

Sea Ice Image Processing

Most of the ice, we called “light ice,” can be identified by Otsu thresholding method. However, the “dark ice,” whose pixel intensity values are close to water pixels, may be lost. To determine more ice pixels, the k -means clustering method is used to divide the image into three or more clusters, considering the cluster with the lowest average intensity value to be water and the other clusters to be ice. The “dark ice” is then obtained

Application of Image Processing in Ice–Structure Interaction, Fig. 14 Maximum floe size entering the protected vessel

Application of Image Processing in Ice–Structure Interaction, Fig. 15 Sea ice image processing result

by comparing the difference between Otsu threshold detection result and *k*-means clustering detection result, as seen in Fig. 15d.

Thereafter, the GVF snake-based floe boundary detection method is run on the image layers of “light ice” and “dark ice” to individually derive “light ice” segmentation and “dark ice” segmentation. Collecting all the segmented ice pieces from both “light ice” and “dark ice” layers, the shape enhancement is then performed to complete the identification. According to section “Ice

Types,” the identified ice pieces are simply distinguished into ice floes and brash ice by defining a brash ice threshold parameter (e.g., number of pixels or area). Then the remaining of detected ice pixels, most of which are the detected boundary pixels between the touching floes, are considered to be “slush.” The sea ice image processing result is then four layers of ice floes (58.00%), brash ice (4.85%), slush (21.21%), and water (15.94%). The processed result of Fig. 15a can be found in Fig. 16, where a total of 2888 ice floes

Application of Image Processing in Ice–Structure Interaction,

Fig. 16 Sea ice image processing result of Fig. 15a

and 3452 brash ice pieces are identified from Fig. 15a.

Sea Ice Numerical Modeling

Based on the image processing results, the identified ice floes and brash ice pieces are further simplified for the numerical simulation of the ice–structure interaction. In this modification, each sea ice floe is represented by a bounding polygon, and the brash ice pieces were reshaped by circular disks of equivalent area (Zhang 2015).

Figure 17 shows an example of sea ice modeling for Fig. 15a. A close-up view of a few ice floes and brash ice in the middle of Fig. 15a is given in Fig. 18, with the blue boundaries of the polygons/circles superimposed on top of the original segmented ice pixels. It is obvious to see that the polygonized floes will not be smaller than the actual identified floes and may overlap with other floes and brash ice pieces. Identifying the overlaps of floe-floe, floe-brash, and brash-brash is important when using the identified ice floes and brash ice as a starting condition for the initialization of an ice field in a numerical simulation for ice–structure interactions (Lubbad et al. 2015). To indicate these overlaps, an “overlap flag” is added to each polygonized floe to record the serial number of the floes and brash ice pieces with which the current floe overlaps and the “overlap flags” of

(a) Polygon fitting to ice floes in Fig. 16(a).

(b) Circle fitting to brash ice in Fig. 16(b).

Application of Image Processing in Ice–Structure Interaction, Fig. 17

Sea ice modeling for Fig. 15a

brash-brash and brash-floe are also registered in this modeling (Zhang and Skjetne 2018).

Ice Field Generation

The numerical representation of sea ice is utilized to generate its corresponding ice field to bridge the

gap between a natural ice field and its numerical applications, e.g., simulations involving ice–structure interactions. A major challenge of utilizing the digitalized ice field is overlaps among ice floes and brash ice. These overlaps are the consequence of both the input image’s visual noise (e.g., the foggy bottom-left corner) and inaccuracies introduced by the adopted image processing technique (e.g., the procedure to polygonize the segmented ice floes). A non-smooth discrete

element method (DEM) is adopted to resolve all the overlaps among different bodies and assign basic physics to each ice floe and brash ice (Zhang and Skjetne 2018; Zhang 2020).

Ice floes are treated as discrete bodies after importing the ice field’s numerical representation into the non-smooth DEM-based simulator, and floe pairs involving overlap are labeled with red color in Fig. 19a. Afterward, for each calculation iteration, the collision detection algorithm identifies existing contacts; and the collision responses are calculated and applied to eliminate the overlaps. Figure 19b shows one snapshot of the ice field domain, within which overlaps are gradually resolved. Notably, for saving computation resources, not all the ice floes are involved in the calculation of each iteration. For ice floes without overlap and that are far away from the overlapped ice floe clusters, they are in “sleeping mode” in the adopted algorithm (see Fig. 19b).

Figure 19a shows that ice floes in the ice field’s bottom-left corner have more overlaps. This is mainly because of the input image’s visual noises.

Application of Image Processing in Ice–Structure Interaction, Fig. 18 A close-up view of floe ice, brash ice, and their corresponding simplifications in modeling

(b) Calculation phase of the ice floe field with overlap.

(c) All overlaps are resolved.

(d) Finally generated ice floe field.

Application of Image Processing in Ice–Structure Interaction, Fig. 19 Ice floe field generation

Application of Image Processing in Ice–Structure Interaction,

Fig. 20 Ice field generation with both floe ice and brash ice

(a) Initial ice condition with overlaps.

(b) Final ice condition without overlaps.

Nevertheless, applying the above non-smooth DEM calculation procedures, all the overlaps are eventually resolved in Fig. 19c, and its corresponding final ice field is shown in Fig. 19d. After resolving the overlaps, the exact location of each ice floe in Figs. 19d and 17a is not the same, but with only minor differences. On the other hand, each ice floe's shape and size and the overall ice field's ice mass are conserved.

Similarly, brash ice can be imported into the same non-smooth DEM-based simulator and be treated as discrete bodies. From a non-smooth DEM calculation's point of view, the simplification of each brash ice as a disk with equivalent area makes the collision detection and consequent collision response calculation much easier comparing to arbitrary polygons. Given the amount of brash ice and its relatively small mass, this simplification is reasonable and has been adopted in previous studies (Konno 2009; Konno et al. 2011, 2013).

For the current demonstration, the identified brash ice in Fig. 16b and its numerical representation in Fig. 17b are additionally imported to the ice field in Fig. 19a. This is illustrated in Fig. 20a, which shows relatively much more overlaps. An enlarged view within the field center is also

presented. The circular disk-shaped bodies are the brash ice representations.

It is computationally efficient to make the circular disk-shaped simplification for brash ices. For the current ice field composition, i.e., 58.00% ice floe and 4.85% brash ice, the calculation time to resolve all overlaps for the cases with and without brash ice poses no significant difference. In both cases, the bottleneck for calculation time is on the overlap resolution in the bottom-left corner's large ice floes. However, it is expected that as the amount of brash ice increases, the calculation time would also increase, which eventually becomes the decisive bottleneck for the calculation. To certain point, it might be more efficient to model brash ice as a continuum, e.g., a viscous flow, which is governed by conservation laws as a material collection.

Conclusion

Various image processing techniques have been introduced in this entry to extract useful ice information from the collected ice image data to support the estimation of ice forces that are critical to marine operations in the Arctic. The introduced

methods have been applied to both model and sea ice image data to give some results applicable for ice engineering. More results and better information of ice from visual images will be investigated by further development of these image processing techniques.

Appendix A Traditional and GVF Snake Algorithms

Traditional Snake Algorithm

A traditional snake is a curve $\mathbf{C}(s) = (x(s), y(s))$ with the normalized arc length $s \in [0, 1]$ that moves through the spatial domain of an image to minimize the sum of the internal and external energy, given by

$$\mathbf{E} = \int_0^1 (\mathbf{E}_{\text{int}}(\mathbf{C}(s)) + \mathbf{E}_{\text{ext}}(\mathbf{C}(s))) ds \quad (11)$$

where $\mathbf{E}_{\text{int}}$ is the internal energy

$$\mathbf{E}_{\text{int}} = \frac{1}{2} \left(\alpha |\mathbf{C}'(s)|^2 + \beta |\mathbf{C}''(s)|^2 \right) \quad (12)$$

where α and β are weight parameters that control the snake's tension and rigidity, respectively. $\mathbf{C}'(s)$ denotes the first derivatives of $\mathbf{C}(s)$ with respect to s , making the snake act as a membrane, and $\mathbf{C}''(s)$ denotes the second derivatives, making the snake act as a thin plate.

$\mathbf{E}_{\text{ext}}$ is the external energy defined in the image domain. It attracts snakes to salient features in the image, such as boundaries. To find boundaries in a grayscale image, $\mathbf{I}(x, y)$, the image gradient is typically chosen as the external energy (Kass et al. 1988):

$$\mathbf{E}_{\text{ext}} = -|\nabla \mathbf{I}(x, y)|^2 \quad (13)$$

where $\nabla \mathbf{I}(x, y) = \left(\frac{\partial \mathbf{I}}{\partial x}, \frac{\partial \mathbf{I}}{\partial y} \right)$ is the image gradient that represents a directional change in the brightness of the image with the gradient angle $\theta = \arctan \left(\frac{\partial \mathbf{I}}{\partial y} / \frac{\partial \mathbf{I}}{\partial x} \right)$. When also considering the

image noise, the external energy is defined as (Kass et al. 1988)

$$\mathbf{E}_{\text{ext}} = -|\nabla \mathbf{G}_\sigma(x, y) * \mathbf{I}(x, y)|^2 \quad (14)$$

where $\nabla \mathbf{G}_\sigma(x, y)$ is a two-dimensional Gaussian function with a standard deviation σ and “*” denotes convolution.

To minimize the energy $\mathbf{E}$, a snake must satisfy the Euler equation:

$$\alpha \mathbf{C}''(s) - \beta \mathbf{C}''''(s) - \nabla \mathbf{E}_{\text{ext}} = 0. \quad (15)$$

Let $\mathbf{F}_{\text{int}} = \alpha \mathbf{C}''(s) - \beta \mathbf{C}''''(s)$ denote the internal force and $\mathbf{F}_{\text{ext}} = -\nabla \mathbf{E}_{\text{ext}}$ denote the external force. Then Eq. 15 can be written as the force balance:

$$\mathbf{F}_{\text{int}} + \mathbf{F}_{\text{ext}} = 0. \quad (16)$$

The internal and external forces are defined such that the snake will conform to an object boundary (or other desired features) within an image. The internal force $\mathbf{F}_{\text{int}}$ discourages stretching and bending, while the external potential force $\mathbf{F}_{\text{ext}}$ pulls the snake toward the desired image boundaries. Eq. 16 implies that the initial curve given in the snake algorithm will move under the influence of internal forces from the curve itself and external forces computed from the image data until the internal and external forces reach equilibrium.

To find a solution for Eq. 15, $\mathbf{C}(s)$ is treated as a discrete system of normalized arc length s and time t :

$$\frac{\partial \mathbf{C}(s, t)}{\partial t} = \alpha \mathbf{C}''(s, t) - \beta \mathbf{C}''''(s, t) - \nabla \mathbf{E}_{\text{ext}}. \quad (17)$$

When the solution $\mathbf{C}(s, t)$ becomes stationary, $\frac{\partial \mathbf{C}(s, t)}{\partial t}$ tends to zero, the energy $\mathbf{E}$ reaches a minimum, and the curve converges toward the target boundary.

The traditional snake algorithm is able to detect weak boundaries. However, there are two key limitations: the capture range of the external force fields is limited, and it is difficult for the

snake to progress into boundary concavities. The traditional snake algorithm is, therefore, sensitive to the initial contour, and the initial contour should be somewhat close to the true boundary.

GVF Snake Algorithm

To overcome the limitations of the traditional snake algorithm, the GVF snake algorithm introduces a spatial diffusion of the gradient of an edge map (which is derived from the image data) to expand the capture range of external force fields from boundary regions to homogeneous regions (Xu and Prince 1998).

The GVF is defined to be the vector field $\mathbf{v}(x, y) = (u(x, y), v(x, y))$ that minimizes the energy functional:

$$\epsilon = \iint \left[\mu (u_x^2 + u_y^2 + v_x^2 + v_y^2) + |\nabla f|^2 |\mathbf{v} - \nabla f|^2 \right] dx dy \quad (18)$$

where u_x, u_y, v_x and v_y are the derivatives of the vector field, μ is a parameter that controls the balance between the first and second term in the integrand, and f is an edge map (which could be the image gradient $|\nabla \mathbf{I}(x, y)|^2$) that is larger near the edges of objects in the image.

In Eq. 18, $|\nabla f|$ becomes large close to the object boundaries, in which case the second term dominates the integrand and is minimized by $\mathbf{v} = \nabla f$. Otherwise, $|\nabla f|$ is small, and the first term dominates the integrand to ensure that the external force field varies slowly and still acts in the homogeneous regions.

The GVF field can be found by solving the Euler equations:

$$\mu \nabla^2 u - (u - f_x) (f_x^2 + f_y^2) = 0 \quad (19a)$$

$$\mu \nabla^2 v - (v - f_y) (f_x^2 + f_y^2) = 0. \quad (19b)$$

A solution to Eq. 19a and Eq. 19b can be obtained by introducing a time variable, t , and finding the steady-state solution of the following partial differential equations:

$$u_t(x, y, t) = \mu \nabla^2 u(x, y, t) - (u(x, y, t) - f_x(x, y)) (f_x(x, y)^2 + f_y(x, y)^2) \quad (20a)$$

$$v_t(x, y, t) = \mu \nabla^2 v(x, y, t) - (v(x, y, t) - f_y(x, y)) (f_x(x, y)^2 + f_y(x, y)^2) \quad (20b)$$

Compared to the external force field in the traditional snake model having only f_x and f_y , the new vector fields, u and v in the GVF, are derived using an iterative method to find a solution for f_x and f_y . The result is that the capture range is effectively enlarged, as seen Fig. 21. Therefore, the GVF snake releases the requirements of the initial contour, so that the initial contour no longer needs to be as close to the true boundary.

Appendix B Distance Transform

Given a binary image $f(x, y)$, whose elements only have values of “0” and “1,” the pixels with a value of “0” indicate the background, while the pixels with a value of “1” indicate the object. Let $B = \{(x, y) | f(x, y) = 0\}$ be the set of background pixels and $O = \{(x, y) | f(x, y) = 1\}$ be the set of object pixels. The distance transform of a binary

Application of Image Processing in Ice-Structure Interaction,
Fig. 21 External forces

image f , $\mathbf{D}(x, y)$ is the minimum distance from each pixel in f to the background B , that is:

$$\mathbf{D}(x, y) = \begin{cases} 0 & \text{if } (x, y) \in B \\ \min_{b \in B} d[(x, y), b] & \text{if } (x, y) \in O \end{cases} \quad (21)$$

where $d[(x, y), b]$ is some distance measure between pixel (x, y) and b (Rosenfeld and Pfaltz 1968).

Appendix C Dilation and Erosion

A dilation operation “grows” or “thickens” objects by adding pixels to the object boundaries. The mathematical definition of dilation of A by B is defined as follows (Gonzalez et al. 2003):

$$A \oplus B = \{z | (\hat{B})_z \cap A \neq \emptyset\} \quad (22)$$

where $(B)_z$ is the translation of B by the point $z = (z_1, z_2)$, defined as

$$(B)_z = \{b + z | b \in B\} \quad (23)$$

and $\hat{B}$ is the reflection of B , defined as

$$\hat{B} = \{w | -w \in B\}. \quad (24)$$

The output of dilation is a binary image having a value of 1 at each location of the origin of the structuring element, such that the reflected and translated structuring element overlaps at least one 1-valued pixel in the input image.

An erosion operation “shrinks” or “thins” objects by removing pixels on object boundaries. The mathematical definition of erosion A by B is as follows (Gonzalez et al. 2003):

$$A \ominus B = \{z | (B)_z \cap A^c \neq \emptyset\} \quad (25)$$

where A^c is the complement of A (0-valued pixels set to 1-valued and 1-valued pixels set to 0-valued, for a binary image), defined as

$$A^c = \{w | w \notin A\}. \quad (26)$$

The output of erosion is a binary image having a value of 1 at each location of the origin of the structuring element, such that the element overlaps only 1-valued pixels of the input image (i.e., it does not overlap any of the image background).

Definition

Various experimental techniques for aquaculture structures have been developed for different purposes. Towing and force oscillation tests on an integrated fish cage system or a single fish net plane are utilized to investigate the mathematical models of the hydrodynamic force coefficients in current and waves, respectively, which are an essential input for numerical simulations. Such experiments can also be implemented in a circulating water channel, which can produce uniform and oscillatory currents. Seakeeping experiment technologies for aquaculture structures in waves and currents are also very popular and have mainly been used for the analysis of the dynamic performance of integrated structures; these technologies can provide important verification data for numerical methods.

Scientific Fundamentals

Experimental Techniques for Aquaculture Structures in Current

In a towing test, an integrated fish cage model or a fish net panel model is installed beneath a towing carriage driven by servo motors. The carriage normally runs at a constant velocity to simulate the pure current in a real sea state. The main purpose is to investigate the hydrodynamic force or deformation for integrating a gravity fish cage or the drag forces of a fish net or semi-submersible fish cage. The circulating water channel test is an alternative approach to the towing test in the simulation of current. The difference is that the model is fixed, and a current with a constant velocity is generated in the water channel.

Experimental Study of a Fish Net Panel in Current

An integrated fish cage can be assumed to be a combination of a number of independent net panels. The drag force on a net cage is then given as the sum of the drag forces on the different net panels. One of the most popular towing experiments on a fish net panel model was conducted by Aarsnes, Rudi, and Løland (Aarsnes et al. 1990). These researchers investigated the flow through and around fish net panels and derived the mathematical function of the drag and lift force coefficient for the screen model with the relation of the solidity ratio and incident current angle:

$$\begin{aligned} C_D &= 0.04 + (-0.04 + 0.33Sn + 6.54Sn^2 - 4.88Sn^3) \cos \theta \\ C_L &= (-0.05Sn + 2.3Sn^2 - 1.76Sn^3) \sin 2\theta \end{aligned}$$

(1)

Here, θ refers to the angle between the vector of the fish net plane and the current direction. Sn represents the solidity ratio. The drag and lift forces acting on the fish net panel can then be calculated as

$$F_D = \frac{1}{2} \rho C_D A U^2; F_L = \frac{1}{2} \rho C_L A U^2 \quad (2)$$

where A is the projected area of the net panel and U represents the current velocity.

Experimental studies of fish net panels have also been investigated by many other researchers. Tsukrov et al. (2011) performed an experimental study of the hydrodynamic forces of copper nets with different solidities, as shown in Fig. 1. Swift et al. (2006) conducted a field test of the drag forces acting on both clean and biofouled net panels. The field testing apparatus is shown in Figs. 2 and 3.

Experimental Study of an Integrated Fish Cage in Current

Towing experiments with integrated fish cages, for instance, a gravity fish cage or a semi-submersible fish cage, have been conducted by many researchers. The main purpose also includes the investigation of the deformation of the fish net, which is slightly different from that in a towing test of the fish net panel.

Lader and Enerhaug (2005) carried out an experiment of a gravity fish cage with a scale ratio of 1:7.1 in uniform current in a water channel driven by four impellers, as shown in Fig. 4. Three different sets of weights with cylindrical shapes made of steel were used in the experiment. The tension in the mooring lines was measured by load cells, and simultaneously, the deformation of the cylindrical net was captured by cameras. The dependency between the forces and the geometry and the effects of the weights on it were the main focus. Kristiansen et al. (2015) performed a model test of a floating fish cage in current in a towing tank, as shown in Fig. 5. The current was simulated by running a towing carriage in calm water.

Experimental Techniques of Aquaculture Structures in Waves

Experimental Study of Hydrodynamic Forces on a Fish Net Panel in Waves

Uncertainties exist if the empirical formula that was developed based on towing experimental data is utilized for predicting the hydrodynamic forces acting on a fish net in waves. Therefore, many researchers have conducted experimental investigations on the hydrodynamics of fish nets in waves. In the experiment, the fish net panel is normally pretensioned in a rectangular steel

Aquaculture Structures: Experimental Techniques, Fig. 1 Experiment apparatus on the hydrodynamic forces of copper nets with different solidities (Tsukrov et al. 2011)

Aquaculture Structures: Experimental Techniques, Fig. 2 Field test apparatus on the drag forces acting on both clean and biofouled net panels (Swift et al. 2006)

framework and then fixed in a water channel. By generating regular or random waves, the wave elevation before and after the net and the

hydrodynamic forces acting on the net panel are measured simultaneously. Compared with the model in the current-only case, two new key parameters should be considered, i.e., the Keulegan–Carpenter (KC) number and wave steepness. These parameters can be written as

$$KC = \frac{\pi H}{D}, \quad s = \frac{H}{L} \quad (3)$$

where H and L refer to the wave height and wavelength, respectively, and D represents the net twine diameter.

Song (2006) performed an experimental study on the effect of horizontal regular waves on fish net panels, as shown in Fig. 6. By using dual series relations, a least squares approximation, and a multiple stepwise regression analysis, this scholar established an empirical relation between the horizontal wave force and the wave period and wave height. Lader et al. (2007) conducted a very similar experiment and measured the forces acting on

**Aquaculture Structures:

Techniques, Fig. 3** A
biofouled net panel (Swift
et al. 2006)

A

net panels with three different solidity ratios when exposed to five different regular wave cases, as shown in Fig. 7. The measurements were compared with three different empirical load models, i.e., a simple drag model, the Aarsnes model, and the Tsukrov model. The simple drag model yielded the best results for two of the net cases for the horizontal forces, while the Aarsnes model gave the best results for the high solidity net. For the vertical force, the Tsukrov model provided the best results.

Experimental Study of Hydrodynamic Forces on a Semi-Submerged Cylinder in Waves

In addition to the fish net, the gravity fish cage also contains a floating collar, which is the main structure resisting wave loads. Slender structures float on the free water surface and continuously undergo locomotion and elastic deformation in waves and current. Although the floating collar is usually made of a circular cylinder and substantial experimental data based on Morison equations are available for the circular cylinder's

Aquaculture Structures: Experimental Techniques, Fig. 4 Deformation of the net cylinder for different weigh configurations and current velocities in a water channel (Lader and Enerhaug 2005)

Aquaculture Structures: Experimental Techniques, Fig. 5 Deformation of the gravity fish cage from towing test in calm water (Kristiansen et al. 2015)

Aquaculture Structures: Experimental Techniques, Fig. 6 Experimental study of fish net panels in regular waves (Song 2006)

hydrodynamic coefficients, it is still difficult to accurately predict the hydrodynamic forces on the floating collar due to its particularities compared with the fully immersed circular cylinder, i.e., the free surface effect.

To understand the hydrodynamic characteristics of floating cylinders, Kristiansen and Faltinsen (2008) conducted research on wave loads on a fixed circular cylinder and the heave and sway motion of a floating cylinder in regular

Aquaculture Structures: Experimental Techniques, Fig. 7 Experiment study of hydrodynamic forces acting on net panel under regular wave (Lader et al. 2007)

Aquaculture Structures: Experimental Techniques, Fig. 8 Experimental study on the wave loads on a cylinder (Kristiansen and Faltinsen 2008)

waves in a wave flume shown in Figs. 8, 9, and 10. In such experiments, the circular cylinder segment model can be fixed or elastically restrained by mooring lines with a specified water depth. As the model is fixed, the main objective is to focus on nonlinear effects such as wave overtopping on the models and how such events influence the wave loads. The experiment makes significant

contributions to the design of gravity fish cages with partially submerged floating collars.

Experimental Study of the Dynamic Response of Fish Cages in Waves

Experimental studies of the dynamic response of a whole fish cage model in waves are essential for the design of aquaculture structures. A physical

Aquaculture Structures: Experimental Techniques, Fig. 9 Photos of a partially submerged cylinder in waves (Kristiansen 2010)

Aquaculture Structures: Experimental Techniques, Fig. 10 Model test of gravity fish cages containing floating tubes (Shen et al. 2018)

model normally contains the fish cage, and the mooring system is arranged in an ocean basin. Regular or irregular waves can be generated by wave makers. The motions of the fish cage model and the tensions in the mooring lines were measured, providing important test data to validate the accuracy of the numerical methods. The procedure is quite similar to that for traditional marine structures. The main difference is the existence of a super-flexible fish net. The physical model of traditional marine structures, such as ocean

platforms or ships, is considered to be a rigid body, and wave actions are dominated by diffraction and mass forces. However, the fish net encounters very large deformations, and the viscous force is dominant. Many researchers have conducted various experimental studies on the wave-induced response of different types of fish cages, such as the gravity fish cage, semi-submersible fish cage, and closed flexible cage. Nygaard (2013) carried out a model test of gravity fish cages containing

Aquaculture Structures: Experimental Techniques, Fig. 11 Model test of a gravity fish cage (Shen et al. 2018)

Aquaculture Structures: Experimental Techniques, Fig. 12 Model test of a semi-submersible fish cage (Zhao et al. 2019)

floating tubes, an elastic sinker tube, a cylindrical net cage, and a mooring system with a scale ratio of 1:16 in irregular wave, regular wave, and current-only cases, as shown in Figs. 10 and 11. Eight linear accelerometers were arranged to capture the deformation of the floating tubes. In addition, axial force transducers were used to measure

the tensions in the mooring lines. Zhao et al. (2019) performed an experimental study of the hydrodynamic characteristics of a semi-submersible fish cage in waves with different wavelengths, as shown in Fig. 12. The motion response and the mooring line tension are measured and used to verify the rationality of the numerical model.

Aquaculture Structures: Experimental Techniques, Fig. 13 Model test of a closed flexible bag (Lader et al. 2017)

Lader et al. (2017) investigated the behavior of closed flexible bags experimentally which is a very new and novel design proposed due to increasing environmental considerations as salmon lice, escape of farmed fish, and release of nutrients. Three different bag shapes with a scale ratio of 1:30 in Fig. 13 were studied: cylindrical, spherical, and elliptical. The response in vertical direction and the tension in the mooring line were measured simultaneously. The deformation of the bag was only recorded qualitatively by using cameras in the test, and no quantitative data were derived from the images.

Forced Oscillation Experiment of Aquaculture Structures

It is hard to get large KC number as real sea state via traditional wave making method. Currently, two ways are available for this problem: one is to force the model harmonically oscillating in still water; another is to fix the model in the oscillatory flow in a U-shaped water tunnel. The latter one is very creative and widely used for the fully immersed cylinder in oscillatory flow. Yet for the cylinder floating on the free surface, e.g., floating collars of the fish farming structures, the waves and current will be always co-existent (where current generally maintains a quite large velocity and hence becomes non-negligible); thus, the wave making and overtopping on the cylinder should be taken into consideration. As the U-shaped water tunnel cannot simulate the free

surface, the first experimental method is presently introduced. Specifically, the forced oscillation of the cylinder fixed on the free surface is used to simulate the water particle motions around the floating cylinder in waves; and the forward towing of the cylinder is used to simulate the steady current speed, so that the effect of the wave making and overtopping can be easily achieved in the experiment.

Fu et al. (2013) and Ren et al. (2019) investigated the hydrodynamic characteristics of the segment model of a floating collar and floater-net system in oscillatory and steady flows through forced oscillation experiments in a towing tank, as shown in Fig. 14. The Reynolds number is from 0.5×10^5 to 7.5×10^5 , and the KC number varies from 6.28 to 37.70. The effects of KC number, Reynolds number, reduced velocity, and overtopping phenomenon on the drag and inertia force coefficients are studied. Also, hydrodynamic forces on the floater and net are compared in detail to analyze their respective contributions to the total drag force.

Key Applications

Experiment of a Fish Net Panel in Waves and Current

An extensive model test of a single net panel in current-only and combined wave and current conditions was performed by J.V. Aarsnes, H. Rudi,

Aquaculture Structures: Experimental Techniques, Fig. 14 Forced oscillation experiment of a partially submerged floating collar (Fu et al. 2013; Ren et al. 2019)

**Aquaculture Structures:
Experimental
Techniques, Fig. 15**

Model test of a single net panel (Løland 1991)

and G. Løland (Aarsnes et al. 1990) at the Ocean Basin Laboratory of Marintek. The experimental apparatus is shown in Fig. 15. The tests were run in a towing tank by mounting the physical model with six different incident angles on the towing carriage. Three different constant towing speeds were used. A full-scale net with dimensions of 1.5×1.5 m and six different solidity ratios was used. A total of 108 possible combinations were carried out for the current-only condition. In the combined wave and current condition, different wave heights, wave periods, and current velocities were used. During the test, the hydrodynamic

forces acting on the net panel in the normal and tangential directions were measured, which were named the drag and lift forces.

By using the experimental data, the drag and lift force coefficients can then be derived by using, for instance, the least squares method, and the empirical relations between the hydrodynamic force coefficients, and the solidity ratios and incident angle can be established, as shown in Eq. 1.

As the flow passes through the fish net, the velocity decreases significantly due to the shielding effect. The quantification of the velocity

reduction is very important for the numerical analysis of the whole fish cage. Therefore, in the model test of the single net panel, the velocity distribution behind the net was also measured, as shown in Fig. 16. An empirical function between the current velocity reduction factor and the drag coefficient was proposed.

**Aquaculture Structures:

Aquaculture Structures: Experimental Techniques, Fig. 17 The experimental arrangement of a gravity fish cage (Shen et al. 2018)

Aquaculture Structures: Experimental Techniques, Fig. 18 From left to right: the gravity fish cage model, the floating collars, the elastic sinker tube, and the buoy (Shen et al. 2018)

Norway, including the floating collars, a fish net cage, an elastic sinker tube, a center point weight, and a mooring system. The mooring system is quite complex and is composed of bridle lines, anchor lines, mooring frame lines, buoys, coupling plates, and anchor lines. The scale ratio is 1:16, and Froude scaling with geometric similarity except for the net twines was adopted. For the net twines, the diameter is too small, and the geometric similarity is almost impossible to satisfy. Only the solidity ratio was designed to be the same as the real-scale structure to ensure the similarity of the hydrodynamic forces acting on the fish net.

A comprehensive measurement system was arranged during the experiment, which includes eight linear accelerometers, fourteen force transducers, and three wave gauges. The tension forces in the bridle lines, anchor lines, ropes connecting the buoy and coupling plate, ropes connecting the sinker tube and net, and ropes in the net cage were measured simultaneously. Furthermore, the motion response and the deformation of the floating collar were captured by using accelerometers. The dynamic response of the gravity fish cage under long-crested irregular

waves, regular waves, and current-only cases was studied.

Force Oscillation Experiment of Floater-Net System

A forced oscillation experiment of floater-net system was carried out by Fu et al. (2014) in a towing tank in Shanghai Ship and Shipping Research Institute in China, which is 192 m long, 10 m wide, and 4.2 m deep; and the maximum velocity of the towing carriage is 9 m/s. The experimental apparatus includes the towing carriage, the forced oscillation apparatus, and a cylinder model, as shown in Fig. 19. The horizontal track length is 3.5 m and the diameter of cylinder is 0.25 m.

The 2 m long smooth cylinder model is manufactured by polypropylene material and installed on the forced oscillation apparatus, passing through two three-component force transducers in use to measure the hydrodynamic force of the floater-net system, as shown in Fig. 2. The model will harmonically oscillate in horizontal direction driven by a servo motor. Oscillating displacement and velocity are controlled according to the experimental design and measured by the encoders of the servo-motor.

Aquaculture Structures: Experimental Techniques, Fig. 19 The experimental apparatus for forced oscillation of a floater-net system (Fu et al. 2014)

Aquaculture Structures: Experimental Techniques, Fig. 20 The arrangement of the measurement system (Fu et al. 2014)

The net is manufactured by nylon material and is 2 m wide and 3.5 m length. The netting is knotless with a mesh size of 20 mm and twine thickness of 2 mm. Mounted as square meshes, the solidity ratio of the netting is 0.4. The net structure is supported by a slender steel rod which is installed on three-component force transducers used to measure the force of net structure, as shown in Fig. 20.

Definition

For *aquaculture structures*, numerical analysis with proper methods is essential for safe structural design. In a numerical method for aquaculture system, a *structural model* and a *hydrodynamic-force model* are needed to describe the structure and evaluate the loads on the structure, respectively. A typical fish-farm system comprises different components, and numerical method for each individual component is required.

Scientific Fundamentals

Traditional Fish-Farm Concepts

There exist a variety of fish-farm concepts, and these concepts can be classified in different ways. For example, Loverich and Gace (1997) classified sea cages into four types based on the structural means used to hold the shape of the cage, i.e., *gravity cages*, *anchor-tension cages*, *semi-rigid cages*, and *rigid cages*. The gravity cages are by far the most widely used concepts in the fish farming industry and thus are explained in detail here. They rely on the force of gravity to maintain net volume, by providing a surface buoyancy system and an underwater weighting system for the net. There exist different materials and geometries of the buoyancy system. The most commonly used are the *circular plastic floaters* and the *interconnected hinged steel floaters*, as shown in Fig. 1.

The cage with circular plastic floaters has been widely investigated; thus a detailed description is given here. The cage typically comprises a *floating collar*, a *net cage*, a *sinker tube*, and a *mooring system*. The floating collar provides buoyancy for the whole system and is common with two nearly semi-submerged concentric circular tubes. The two tubes are held together by steel brackets. The usage of the net is to protect the fish from predators and provide a suitable habitat. The net is highly flexible, so it will experience deformation when subjected to external loads from waves and current. A bottom weight ring (sinker tube) is often attached to the cage bottom to ensure sufficient volume of the net cage. In reality, there exist multiple cages at real sites with cages arranged in mooring grid in single or double rows. This will have an influence, for instance, on the steady inflow (current) due to the *shadowing effects* from the upstream cages, compared with a single cage system. The mooring system normally used by the circular cages is a square-shaped grid system held on the seabed with an array of mooring lines. The mooring lines include the anchors, ground chains, ropes and related shackles, and buoys (Shen 2018).

Aquaculture Structures: Numerical Methods, Fig. 1 Left: circular plastic cage. Right: hinged square steel cages. (Source: www.akvagroup.com/news/image-gallery)

Novel Fish-Farm Concepts

There exist multiple challenges for the fish-farm industry nowadays. One of the big problems has been the rise of sea lice. It has become increasingly serious as the sea lice have become more resistant to chemicals used to treat them. Escaped fish is another concern. In addition, due to limited nearshore area and increasing impact to the local ecosystem, the aquaculture industry is trying to move the marine fish farms from nearshore to more exposed sea regions where waves and current are stronger. To meet the challenges faced by the fish-farm industry, new fish-farm designs are emerging. *Closed fish-cage concepts* are proposed to have a better control over the water quality and especially to avoid the problem of salmon lice. *New open-cage fish-farm* concepts are also under development to operate in more exposed sea regions or even in open sea, by combining the best of existing technology and solutions from the Norwegian fish farming industry and the offshore oil and gas sector (Shen 2018).

Historical Development (Traditional Fish Farms)

Many numerical and experimental investigations have been performed during the past decades to examine the behavior of traditional aquaculture fish farms under waves and current. The fact that the netting may have ten million meshes limits the implementation of computational fluid dynamics (CFD) and complete structural modeling. Therefore, rational simplifications are often needed. Important literatures for the modeling of the

different components of a traditional fish-farm system will be introduced. The focus will be on the *structural* and *hydrodynamic* modeling of the floating collar and the net cage.

The Floating Collar

The floating collar of a sea-cage is typically composed of two concentric elastic pipes interconnected by brackets and a handrail. The structure is often modeled into a single or double column pipe without the handrail. When estimating the hydrodynamic loads on the floater, *rigid body* is commonly assumed and *strip theory* is adopted, disregarding important three-dimensional (3D) flow, frequency-dependency hydrodynamic coefficients, as well as nonlinear effects in steep waves. *Modified Morison's equation* (Brebba and Walker 1979) was widely employed to calculate the load on each collar segment (see Fig. 2), for example, by Huang et al. (2006), Zhao et al. (2007a), Dong et al. (2010a), and Cifuentes and Kim (2017).

Dong et al. (2010b) tried to incorporate the *elasticity* of the floater into the modeling and proposed an analytical method to analyze the elastic deformations of a circular ring in waves. The governing equations of six degree-of-freedom rigid-body motions and elastic deformations were obtained according to Euler's laws and curved beam theory.

Faltinsen (2011) pointed out that the diffraction and radiation effects may matter for the response of the floater. He derived an analytical formula for the added mass for different modal of an elastic floater based on a slender body theory

Aquaculture Structures: Numerical Methods, Fig. 2 Left: a sketch of the float-collar system. Right: a sketch of the float collar mini-segment (Dong et al. 2010a)

and rigid free-surface condition. Li and Faltinsen (2012) calculated the vertical added mass, damping and wave excitation loads on an elastic semi-submersible torus based on low-frequency slender-body theory. They found that three-dimensional (3D) flow, hydroelasticity, and strong hydrodynamic frequency dependency matter on the scale of the torus. The structural response of the floater was modeled using the principle of modal superposition. The numerical model from Li and Faltinsen (2012) was further adopted to investigate vertical accelerations of a moored floating elastic torus without netting in regular waves (Li et al. 2016, 2018b), an aquaculture net cage with floater in regular waves and current (Kristiansen and Faltinsen 2015), and a realistic marine fish farm in waves (both regular and irregular) and current (Shen et al. 2018).

Commercial structural software could also serve as an alternative tool to investigate the deformation of the floating collar. For example, Fu et al. (2007) used the extended three-dimensional (3D) hydroelasticity theory to predict the hydroelastic response of flexible floating interconnected structures, including displacement and bending moments under various conditions. The finite element method (FEM) solver ABAQUS was used as the eigen-solver. Fu and Moan (2012) applied the same theory in the frequency domain to predict the dynamic response of the 5-by-2 floating fish-farm collars in regular waves. Liu et al. (2019) evaluated the structural

strength and failure for floating collar of a single-point mooring fish cage based on FEM solver ANSYS.

Computational fluid dynamics (CFD) calculations were also performed to calculate the hydrodynamic loads on the floater. For instance, Kristiansen (2010) presented model test results in two-dimensional (2D) flow conditions of a semi-submerged floater without netting in regular waves and validated a CIP (Constrained Interpolation Profile)-based finite difference method that solved Navier-Stokes equations for laminar flow. Similar approach was implemented by Bardestani (2017) to investigate the snap loads in the netting in two-dimensional conditions in waves.

The Sinker Tube

The sinker tube can be modeled in a similar way as the floating collar. For instance, the structure can be described by the curved beam equations, and the hydrodynamic loads can be estimated by the modified Morison's equation (Shen et al. 2018).

The Net Cage

In order to analyze a net in current and waves, one needs a *structural model* and a *hydrodynamic force model*. In *structural analysis* of nets, it is difficult to fully simulate the strong fluid-structure interaction between moving seawater and the highly flexible net. To reduce complexity, the nets are often represented by some *equivalent*

structural elements, e.g., truss, beam, cable, or spring elements. To guarantee that equivalent twine has the same drag force, buoyancy, gravity, and stiffness as the original netting, the equivalent element is given a certain length and diameter such that it has the same projected area as the physical net it represents. In this way, the number of twines can be reduced to a great extent.

For the hydrodynamic loads acting on the net, although computational power has increased significantly, it is still not practical to apply CFD approach to simulate the full nets system with order of ten million. Two main types of hydrodynamic-force models are typically applied to predict viscous loads on nets, i.e., *Morison model* and *screen model*. The first method is to model the net as individual knots and twines, calculating the total drag on the net as sum of the drag contributions of individual elements, without considering the interaction between twines. *Morison's equation* is used to calculate the cross-flow force on each twine based on cross-flow principle. There are two limitations for the Morison model: (1) a drag model based on the cross-flow principle cannot be justified when the inflow angle is larger than about 45° and (2) the interaction between the twines is not accounted for. The second method is to assume that the net is made of surface elements with properties accounting for the underlying twine and knot structure. The hydrodynamic force is decomposed into a normal and a tangential force component on the net panel (Kristiansen and Faltinsen 2012).

The Morison-force model: The literatures described next applied *Morison-force model* with different structural modeling. Theret (1993) proposed an original 3D numerical model for modeling fishing nets in steady current using rigid cylindrical bar/truss elements. Bessonneau and Marichal (1998) generalized the method proposed by Theret (1993) to investigate the steady shape of submerged trawl nets. The rigid net twines were further divided into two sub-elements, allowing the twines to buckle/loose when subjected to compression (see Fig. 3). The *mesh grouping method* was proposed to reduce the number of unknowns in which several actual meshes were grouped into a fictitious equivalent mesh having the same specific mass, apparent weight, and approximately the same drag resistance.

Li et al. (2006) developed a numerical model, based on a *mass-spring method* (see Fig. 4) to investigate the hydrodynamic behavior of submerged plane nets in current. The method is similar to Bessonneau and Marichal (1998), except considering also the netting elasticity. The fishing nets were modeled as a series of lumped point masses that were interconnected with springs without mass. The model was validated and applied to several other problems, such as a three-dimensional cage with rigid floater in current (Zhao et al. 2007a), in combined regular waves and current (Zhao et al. 2007b) and in irregular waves (Dong et al. 2010a). The method was also implemented to the analysis of

Aquaculture Structures: Numerical Methods, Fig. 3 Decomposition of rigid elements of diamond mesh nettings (Bessonneau and Marichal 1998)

Aquaculture Structures: Numerical Methods, Fig. 4 The schematic diagram of the mass-spring model (Li et al. 2006)

hydrodynamic behavior of multiple cages in combined wave-current flow (Xu et al. 2013). Similar strategy was chosen by Lee et al. (2008) to simulate a fish cage system subjected to current and waves.

Tsukrov et al. (2003) showed that hydrostatic and hydrodynamic forces exerted on the moving netting, including wave and current-related water motion, cannot be exactly represented by *equivalent structural elements*. They developed a special *consistent net element* to model net panels or their parts. The method was further applied, for instance, to the analysis of a four-cage grid mooring for open ocean aquaculture (Fredriksson et al. 2003, 2004), the prediction of the dynamic response of a single-point moored submersible fish cage under currents (DeCew et al. 2010), and the evaluation the distribution of tension in a two-dimensional net panel (Fredriksson et al. 2014).

Commercial FEM program could also be used to analyze the deformation of the net twines. For example, Gignoux and Messier (1999) proposed an algorithm based on the introduction of the mapping coefficient and successfully applied the model to aquaculture nets using ABAQUS/Aqua beam elements. Moe et al. (2010) used ABAQUS to analyze the deformation of a net cage in currents. ABAQUS was also employed to analyze nonlinear hydroelastic of an aquaculture system, subjected to current, regular, and irregular waves (Li et al. 2013a, b).

The screen-force model: The literatures next describe the development of *screen-force models*, which are gaining increasingly attention. Schubauer et al. (1950) derived theoretical models based on experimental data for the normal and tangential forces acting on screens inclined to steady ambient flow. The examined inclination angle varies between 0° and 45° . Milne (1972) derived an empirical formula for the drag coefficient of plane nets in a steady current as a function of net geometry.

Løland (1991) presented empirical formulas for the drag and lift on planar net panels, known as *Løland's formulas*. The drag and lift coefficients were given as function of solidity ratio and inflow angle for a limited range of *solidity ratio* (0.13–0.317). The *solidity ratio* of a screen is the ratio of the area projected by the screen on a plane parallel to the screen, to the total area contained within the frame of the screen. The *inflow angle* is the angle between current velocity and the normal direction of net panel. The coefficients in the formulas were determined by curve fitting experimental data from Rudi et al. (1988) obtained by towing net panels.

Lader et al. (2003) proposed a dynamic model for 3D net structures exposed to waves and current, based on a *super-element formulation*. In the method, the net structure was divided into four-sided super-elements interconnected in each corner node (see Fig. 5). The hydrodynamic and structural forces were calculated on each super-

Aquaculture Structures: Numerical Methods, Fig. 5 Super-element. Left: element area. Right: the structural model of the element. Node numbers are indicated in circles and spring numbers in squares (Lader et al. 2003)

element, and the total forces were collected in each node where the equations of motion were solved. The hydrodynamic forces on each super-element were calculated based on empirical formulas from Løland (1991). The structural forces were calculated by assuming that each element consists of six nonlinear springs, interconnecting each node to the other three. The super-element method was further utilized to calculate the responses of a flexible net sheet in waves and current (Lader and Fredheim 2006).

Huang et al. (2006) developed a numerical model to simulate the dynamic properties of a net cage system in current based on a screen-force method. In their model the net cage was divided into several plane surface elements to calculate the external forces. The external force was calculated on each element and then equally distributed to its nodes. The drag and lift force coefficient for the net plane was based on the Løland's formulas (Løland 1991).

The screen model proposed by Løland (1991) was further generalized by Kristiansen and Faltinsen (2012), taking into account also the effect of *Reynolds number*, i.e., the force components on a panel are functions of *solidity ratio*, *inflow angle*, and *Reynolds number*. The relevant *Reynolds number* is that based on the physical twine diameter. A uniform turbulent wake was assumed inside the cage based on the theoretical

formula proposed by Løland (1991) for cross-flow past a plane net, leading to a *flow reduction* in the rear part of the net cage. The dynamic elastic truss model by Marichal (2003) was used to describe the net structure. The screen-force model was further adopted to investigate an aquaculture net cage with floater in regular waves and current (Kristiansen and Faltinsen 2015), a realistic marine fish farm in waves (both regular and irregular) and current (Shen et al. 2018), the influence of well boat on aquaculture system (Shen et al. 2019a, b), and the influence of fish in a net cage on mooring loads (He et al. 2018).

Recently, Cheng et al. (2020) presented a systematic review of hydrodynamic models for the net cage, including five Morison models and six screen models. All the models were incorporated into a general finite element (FE) solver for comparison purpose and suggestions for selection of suitable hydrodynamic models were provided.

Computational fluid dynamics (CFD): With the increasing computer resources, growing attention is paid to implement the computational fluid dynamic (CFD) approach to evaluate the flow inside and around a fish cage. During CFD simulations, the net is modeled as a porous media with the influence of the net represented by a resistance term, neglecting the detailed geometry of the net structure. The corresponding resistance coefficients can be obtained from empirical formulas

(*Morison model* and *screen model*) or laboratory experiments. For instance, Shim et al. (2009) investigated the flow through and around a circular cylinder cage using the commercial software Fluent. The net and frame were represented by a porous jump boundary condition, and the pressure drop coefficients were determined through towing tests. Similar approach was adopted by Patursson et al. (2010) and Zhao et al. (2013) to model the flow around a fixed net panel. Attempts have also been made to take the influence of the structural deformation into consideration by coupling the structural model with the porous media model to achieve fluid–structure interaction (FSI) analysis (see Bi et al. (2014a, b) and Yao et al. (2016) for the net under steady current and Chen and Christensen (2017) and Bi et al. (2017) for the net under waves).

The Mooring System

The complete set-up of the mooring system typically comprises ropes and chains, with buoys to support all mooring lines. The buoys are floating circular cylinders and can be modeled by classical seakeeping theory (see Endresen et al. (2014)). Ropes and chains can be treated in a similar way as the net and modeled as elastic trusses/beams with correct diameter, weight, and stiffness. The hydrodynamic forces on the mooring lines can be estimated by a modified Morison's equation based on the cross-flow principle (Shen 2018).

Historical Development (Novel Fish Farms)

As mentioned, the expansion of nearshore fish farming becomes difficult due to limited space and increased environmental impact. This drives the growth of offshore fish farming. Several *new open-cage fish-farm* concepts have been designed and tested to operate in offshore sites. *Closed fish-cage concepts* are also under development to get rid of salmon lice. Important numerical investigations performed recently for these concepts will be described in the following.

Open-Cage Fish Farm

To withstand large wave actions, offshore fish farms are generally with large floating structures,

constructed from steel. These structures can in many ways be compared to platforms from oil and gas industry. Thus, numerical analyses can be conducted through a combination of the same kind of procedures as for offshore platforms and the approach for the fish net.

Bore and Fossan (2015) performed ultimate and fatigue limit state analyses of ocean farming's rigid offshore aquaculture structure. The concept consists of a twelve-sided, cylindrically shaped frame with a net attached to (stretched over) the sides and bottom. This makes up the hull and the fish cage. A Morison model was used for calculation of hydrodynamic forces on all the components. Similar structure was considered by Shi (2019), but with slight modification to operate in Chinese ocean. Morison equation was applied to estimate the viscous loads on slender members. For the pontoon with large dimension, the radiation and diffraction effects may matter; thus the corresponding hydrodynamic forces were evaluated based on a linear potential theory.

Li and Ong (2017) presented a preliminary study of a rigid semi-submersible fish farm for open seas. The farm comprises a lower and upper pontoon with vertical and diagonal bracing in between. The net cage is connected with the lower pontoon and is totally submerged to avoid large wave loads close to the surface. The linear hydrodynamic properties for support structures using different composite models with panel and Morison elements were computed. The nets were simplified as rigid slender elements. This simplification neglects the net deformations and may overestimate the hydrodynamic forces and viscous effects from the nets. Based on the hydrodynamic analysis, linearized frequency-domain and coupled time-domain analysis were performed to predict the extreme motions of the support structure and the extreme tensions in the mooring lines. Similar approach was followed by Li et al. (2018a) to investigate a vessel-shaped offshore fish farm under various wave and current conditions. The effect of current velocity reduction due to shielding effects from upstream cages was also discussed.

Closed-Cage Fish Farm

Closed fish cages can be divided into flexible cages, semi-flexible cages, and rigid. They have typically a vertical symmetry axis at rest. The water inside a closed cage causes statically destabilizing roll and pitch moments. Wave-induced sloshing (interior wave motion) becomes an issue as well-known from many engineering applications. Since marine applications involve relatively large excitation amplitudes, resonant sloshing can involve important nonlinear free-surface effects. The viscous boundary layer damping is very small. However, if breaking waves occur, the associated hydrodynamic damping is not negligible (Faltinsen and Shen 2018).

Linear response of a 2D *closed flexible* fish cage in waves was investigated by Strand and Faltinsen (2019). The motion of the membrane was represented as the sum of rigid body motions and Fourier series with zero displacement at the attachment to the floater. Linear frequency-domain potential flow theory of incompressible water was used both for the interior and external flows. Strong coupling between elastic modes and rigid body motions was observed. The approach was extended to investigate linear wave-induced dynamic structural stress of a 2D *semi-flexible closed* fish cage (Strand and Faltinsen 2020). They compared a quasi-static analysis with a fully coupled hydroelastic analysis to examine the soundness of assuming that the stresses in the structure is quasi-static. They found that the necessity of performing a hydroelastic analysis depends on the stiffness of the structure.

Kristiansen et al. (2018) conducted a numerical and experimental study on the seakeeping behavior of a floating *closed rigid fish cage* with cylindrical shape. The focus was on effects of sloshing on the coupled motions and mooring loads. Dedicated scaled model tests of closed cages in waves were presented and compared with numerical simulations using *linear potential theory* in frequency domain. The results showed that the influence of sloshing on the rigid body motion was significant. Mean wave loads were also affected by sloshing. Similar

cage concept was examined by Tan et al. (2019). The sloshing inside the cage was described by the single-dominant *nonlinear multimodal theory* presented in Faltinsen and Timokha (2009). They demonstrated that the nonlinear swirling waves due to the interactions between different sloshing modes could only be explained by a proper nonlinear theory.

Definition

Arctic pipelines refer to pipelines that pass through a permafrost, where the soil or rock remains below 0 °C throughout the year and the formation is sufficiently cooled during the winter to form a layer that persists throughout the summer.

Introduction

The Arctic has enormous resources in permafrost, which need to be developed by being highly aware of the possibility of environmental damage. Permafrost currently accounts for about a quarter of the Earth's land area. Figure 1 shows the distribution of permafrost regions in Alaska, which have large areas of permafrost (Larsen et al. 2008). Arctic pipelines refer to pipelines that pass through a permafrost, where the soil or rock remains below 0 °C throughout the year, and the formation is sufficiently cooled during the winter to form a layer that persists throughout the summer. The main characteristics of arctic pipelines are determined by the climatic conditions pertaining to a given territory, which are described below, and it may be noted that some of these features can be encountered in territories outside of the polar circle, low radiation balance, summer average zero temperature, annual average subzero temperature, large areas of permafrost, wet lands, and an abundance of swamps in plains.

Normally, Arctic pipelines are pipelines transporting gas and oil from production sites to the facilities. What's more, arctic pipeline applications also include unprocessed well fluid and utility lines, processed oil and gas pipelines, combined offshore/overland pipeline systems, subsea field developments, cables, and umbilicals.

The configurations of arctic pipelines include single-walled steel pipe, pipe-in-pipe, flexible pipe and pipe-in-HDPE pipe, etc.

Following BP's discovery of oil in Prudhoe Bay oil field near the Arctic Ocean coast in 1968, the Northstar Pipeline was proposed. This pipeline construction was the first long pipeline construction in Arctic area; prior to this project, only short pipelines were built only in areas such as Siberia and Norman Wells on the Mackenzie River in Canada. With the development of technology and the rise of oil price in the early of the twenty-first century, lots of Arctic pipeline projects were constructed in recent years.

Advancement of Arctic Pipeline Design Technologies

In the Arctic pipeline design, it requires emerging technologies to balance between the efficient and economical design and installation of pipelines in the Arctic. Some early analyses used to evaluate Arctic loads on pipelines apply to those specific projects; but as industry enters more severe Arctic conditions, advancements need to continue to ensure a proper balance between safety and economics. Expanding international knowledge about Arctic conditions, improvements in material behavior, advances in analytical techniques,

Arctic Pipeline,

Fig. 1 Arctic areas of Alaska permafrost coverage (Yong Bai et al. 2014)

and broad acceptance of progressive design concepts, such as strain-based design and the implementation of reliable Arctic operational strategies, enable the consideration and development of other offshore Arctic prospects (Paulin and Caines 2016).

Probabilistic Design Approaches

Based on historical data from a given area and water depth, an ice scouring or structural scour depth statistic assessment can be used to predict extreme ice wash or structural scouring depth at a particular acceptable risk level. However, probabilistic analysis which only considers numerical statistical modeling does not evaluate methods for obtaining data, ice wash, or structural washout depth resolution cutoffs, effects of dynamic environmental activities, pipe and scour direction, scour or flush recurrence rate, pipe length, and other factors. In many instances, gouging is considered the most important loading condition for offshore pipeline design, but it is also considered the most uncertain in terms of predictability (Liberty Energy Project 2017) (Fig. 2).

Finite Element Methods

When a buried pipeline is subjected to a large deformation load, the strain in the pipe wall may be higher than that allowed by conventional design specifications based on linear pipe behavior. In fact, pipeline behavior is nonlinear due to

the potential for large deflections and plastic material properties. Therefore, it is necessary to complete the limit state by including geometric and material nonlinearity, strain-based design. Finite element analysis allows modeling nonlinearities in material, geometry, and tube-soil interactions; it has been used to assess the integrity of pipelines in environmental loading events, such as ice scouring, permafrost melt settlement, frost heave, bulge buckling, and free span of structural scour.

INTECSEA, for example, has developed in-house subroutines for the CEL Advanced Constitutive soil models that more realistically simulate the soil behavior based on critical state soil mechanics theory. These models can address dilation issues and hardening/softening behavior of the soil which results in more accurate estimation of subgouge deformations under ice scour loads. An example of a resultant axial strain due to deformation is shown in Fig. 3.

Industry Regulations, Standards, and Codes

Following regulations, standards, and codes are widely used in offshore Arctic pipeline design.

Arctic Specific Regulations

1. ISO 19906 (2010 Edition) Petroleum and Natural Gas Industries-Arctic Offshore Structures

4. DNVGL-ST-F101 (2017 Edition) Submarine Pipeline Systems

Existing Arctic Pipelines

The existing Arctic pipeline projects include single-walled project: Northstar (Alaska), Varandey Oil Terminal (Russian Pechora Sea), Baydaratskaya Bay Pipeline, Crossing (Russian Kara Sea), Sakhalin 1 (Russian Sea of Okhotsk), Sakhalin 2 (Russian Sea of Okhotsk), Kashagan (Russian North Caspian), and pipe-in-pipe project: Drake Project (Canadian Arctic Archipelago), Oooguruk (Alaska), Nikaitchuq (Alaska), and Liberty Proposal (Alaska). They provide important experience base for designing, installing, and operating future offshore Arctic pipelines. Figure 4 shows the location of these projects.

Figure 5 provides design details for the three operational Alaskan offshore pipelines/flowline bundles.

Northstar

The Northstar pipelines which production commenced in October 2001 were designed for ice

Arctic Pipeline, Fig. 4 Alaskan offshore projects

keel gouging using empirical methods. Limit state strain criteria were developed for design of non-cyclic pipeline displacements settlement, with allowable strain levels established based on the pipe dimensions and material grade.

The pipeline system was made up of a single-walled oil pipeline and a single-walled injection gas pipeline; they were installed in a common trench which the maximum design burial depths reach 7 ft below seabed to top of pipe between, with winter construction using conventional onshore equipment (Paulin et al. 2001) (Fig. 6).

Oooguruk

Natural Resources Alaska Inc. developed the Oooguruk field on the Alaskan North Slope, using a buried three-phase flowline following a pipe-in-pipe design approach from the gravel island to shore, which includes 12 in by 16 in PIP production, 8.625 in OD water injection, 6.625 in OD gas, and 2 in OD AHF line (Lanan et al. 2008). The pipe-in-pipe concept was chosen for the purpose of insulating the production flowline. An added benefit of the vacuum annulus was its

availability as a leak detection system for the offshore production flowline (Fig. 7).

Nikaitchuq

Eni Petroleum Corporation developed the Nikaitchuq field located south of Spy Island in the Beaufort Sea. Produced fluids are transported to shore from the Spy Island drill site via a buried three-phase flowline to a production facility located at Oliktok Point.

The Nikaitchuq flowline bundle is made up of a 14 inch by 18 inch PIP flowline carrying produced fluids, a 12 in OD water injection line, a 6 in OD spare flowline, and a 2 inch by 4 inch PIP Arctic heating fuel line. The PIP concept was mainly chosen for the purpose of insulating the flowline, with the added benefit of allowing annular monitoring for leak detection (Paulin et al. 2001) (Fig. 8).

Arctic Pipeline Design Challenges

Pipeline configurations for Arctic pipeline design, thermal insulation, and trenching requirements

Arctic Pipeline, Fig. 5 Alaskan offshore pipelines/flowline bundles design details (Lanan et al. 2015)

A

Arctic Pipeline, Fig. 6 BP Alaska Northstar Gravel Island (Paulin et al. 2001)

Arctic Pipeline, Fig. 8 Nikaitchuq Spy Island drill site (Paulin et al. 2001)

are affected by Arctic environmental load conditions. The main features of pipeline design in the Arctic or Arctic environment include pipeline environmental loads and extreme state design under extreme load conditions, resulting from ice scour. Ice scouring is often referred to as the geological term for long and narrow ditches on the sea floor, caused by the grounding of fast ice, fast ice, and pack ice. The differences between arctic pipelines and other conventional pipelines include operating temperature; geotechnical loads, resulting from thaw settlement and frost heave; construction surface disturbance impacts on permafrost terrain; seasonal constraints on construction and maintenance activities; and civil construction techniques in permafrost.

The differences due to the climate conditions and ice coverage require the consideration of certain challenges in the design of arctic pipelines, which include ice scouring, strudel scouring,

permafrost thaw settlement, frost heave, pipe-soil interaction, monitoring and leak detection in the Arctic, and construction and installation techniques. What's more, ice scouring, strudel scouring, and permafrost thaw settlement phenomenon are shown in Figs. 9, 10, and 11, respectively.

Based on the existing development and research of Arctic pipelines, probabilistic design method and finite element analysis method are used to predict the design principles and layout of Arctic pipelines.

Firstly, the probability design method is used to estimate the reliability range of the design of the Arctic pipeline, and then the finite element analysis method is used to accurately calculate and evaluate the reliability of the design of the Arctic pipeline within the reliability range. Through a lot of calculation and comparative analysis, the design principles and layout of the Arctic pipeline are summarized.

Arctic Pipeline, Fig. 9 Ice keel scouring over a pipeline

Arctic Pipeline, Fig. 10 Strudel scour over a pipeline

Arctic Pipeline, Fig. 11 Thaw settlement and frost heave

The differences due to the climate conditions and ice coverage require the consideration of certain challenges in the design of arctic pipelines, while include:

Ice gouging or icebergs in shallow water
Strudel scour
Frost heave
Permafrost thaw settlement
Upheaval buckling

The main concerning limit states to be investigated during the design of arctic pipelines are two types of limit states. One is the limit state of the rupture of a pipe wall that causes leakage of hydrocarbons, in which the ultimate limit state is thresholds beyond which pressure containment, safety, or the environment is threatened. Another one is the limit state of accident conditions where the pipeline no longer meets one or more design requirements. The serviceability limit states are reached, and the normal operations are restricted, which leads to economic damage to the operator. The goal of the limit state design is to verify the adequacy of the pipeline design against limit states and failure modes relevant to the events. The criteria from DNV OS-F101 and API RP 1111 may be considered. Criteria from these references are based mostly on the risk principles and limit state methodology. The following limit states are to be considered for the design of arctic pipelines: compressive strain limit states for local buckling, tensile strain limit states for strain capacity, and fracture.

Arctic Pipeline Design Procedure

The arctic pipeline design for frost heave and thaw settlement may be carried out through an iterative process in the following steps:

1. Hydraulic analysis for establishing the relationships among the pipe size, material grade, wall thickness, operating temperature, and pressure profiles.
2. Geothermal analysis to predict the potential for frost heave and thaw settlement by using an operating temperature profile. A range of route conditions based on the statistics in terrain analysis are considered as well.
3. Structural modeling to predict pipeline strain and displacement distributions resulting from predicted frost heave and thaw settlement effects over time.
4. Determination of the pipe's capability to sustain the strain and displacement through the analysis of finite element modeling and full-scale test results.
5. Comparison between the strain demands over time with the strain capacity to ensure the pipeline integrity.
6. Testing and checking the heave frost and thaw settlement displacements and freeze bulb growth to assess the environmental impacts.
7. Evaluation of the following factors to the design and maintenance of the arctic pipeline, such as temperature limits, material grade of pipeline, pipeline size, and wall thickness.
8. Repeating Step 1 until Step 7 as required. Arctic pipeline designs also need to include parameters such as ice impact, gouging by icebergs or ice keels, assessment of uncertainty related to ice scour events, and ice-soil-pipe interaction.

Future Arctic pipeline design principles and layout can be predicted on the existing Arctic pipeline development and research.

Definition

An **Atmospheric Diving Suit (ADS)**, also known as **Atmospheric Diving System**, is a humanoid type deep-sea manned operation system, which can maintain atmospheric pressure when diving. The diver equipped with the suit can directly reach the operation site for observation, navigating by the underwater thruster, or landing and shifting by its own strength. At the same time, with the help of rotary joints, divers can control the gripper of both hands and special tools under underwater operations. The suit is connected to the Tether Management System (TMS) through the neutral cable to obtain energy and communicate. The video image of the operation process is also transmitted to the surface ship for the personnel to make a decision for reference (Jiang et al. 2013c).

Scientific Fundamentals

Historical Development

As a common underwater operation equipment, ADS has been progressed with the development of human technology. Since the simple “diving tub” developed by John Lethbridge in 1715 for the salvage of underwater wreck, to the Hardsuit2000 equipment for submarine rescue, it has experienced 300 years of history (Thornton 2000). In recent years, with the development of offshore oil industry, the ADS in various countries is developing rapidly. Its submergence ability can descend to depth steadily from more than 10 m

to 600 m; from single observation ability to complicated operational ability with professional tools; ADS provide a guarantee in wide application fields in deep-sea oil and gas resources and salvaging of sunken ships.

Early Development of ADS

The birth of the first kind of diving suit 1715 to 1882 *Carmagnolle* can be thought of as the early development of ADS. At this stage, the development was mainly driven by salvaging sunken wreck treasure, while technical level at a very low level. Shallow operation depth, no life support systems, or just through the air pipe connecting to the surface, no communication system, no propulsion system, small size and flat glass-viewing window are the typical characters. However, it was during this period, the concept of atmospheric diving for underwater operations, and gradually from the initial bucket structure development to the humanoid type structure, from the development of wooden materials to metal materials, emerged from without limbs joint to the primary of the joints. In this period, *Lethbridge*, *Taylor*, *Phillips*, *Carmagnolle* (Yang 2015) successively appeared.

In 1715, John Lethbridge sought a way to acquire wealth by building a device to recover some of the treasures from the sunken ships (Aylmer 1996). The *Lethbridge*, which he calls “a submersible that is not connected to air,” is widely considered to be the early embryo of ADS. In fact, it is only a wooden bucket that is suspended into the water, through the wall of the bucket with both hands and set up sealing measures to carry out the normal pressure diving.

In 1838, the first diving suit equipped with joints, *Taylor*, was designed. See Fig. 1. Divers in *Taylor* connected with the water supply through a hose, and the joint is similar to the steel structure of accordion type, leather material helping water-tight (Harris 1985). These types of joints have only limited ability in a small range of activities and shallow water depth.

Phillips, designed in 1856, was the first fully enclosed diving suit (Davis 1951) and ball-hole joint was first used. There is a buoyancy chamber on the back, a single-hole viewing window,

Atmospheric Diving Suit (ADS), Fig. 1 Taylor atmospheric diving suit design, 1838 (Harris 1985)

a manhole on the top, and a simple clamping device on the upper extremity, all of which are standard modern fixtures. There is no record of the *Phillips* being built, but many of its features have been applied to successful installations over the next century.

Carmagnolle is the most famous ADS of this stage. In 1882, the Carmagnolle brothers applied for the patent of armored diving equipment in France. The joint of the device is tightly assembled from several concentric hemispheres and is attached to each other by a water-tight cloth with a certain folding so that it can slide (Davis 1951). This is the first truly constructed humanoid assembly, and it is the first time to introduce the Ergonomics consideration in the design.

Mid-Term Development of ADS

After the development of the previous stage, ADS is already applied in wider fields, such as underwater operation of marine oil and gas industry, and aid to the navy submarine rescue. The ADS system also tends to be improved gradually, equipped with independent life support system, communication system, propulsion system, and

operational tools. In this period, there were two important types of joints – oil filled spherical joint and oil filled cylindrical joint, bringing leap-forward development. With materials of steel, magnesium alloy, aluminum alloy, and glass fiber reinforced plastic applied, the operation depth of ADS has been developed from several meters to hundreds of meters. With the enhancement of the underwater working ability of the suits, it is gradually recognized by the industry. Some types have also developed from a single prototype in the early stage to an industrial production status. During this period, many different types emerged, such as *Bowdoin*, *Neufeldt & Kuhnke*, *Galeazzi*, *Campos*, *Peress*, and *JIM* (Yang 2015).

In 1915, American Bowdin obtained a patent for a new type of oil-filled rotary joint. The joint is cylindrical and has a small catheter that equates the internal and external pressure. However, without lasting lubrication, the joints can easily get stuck (Harris 1985). Although this device was not manufactured, it introduced a very important concept of oil filled pressure balance and played an important role in the development of the joint. Then in 1922, Victor Campos applied for a patent for a similar type of oiled joint and made *Campos*. The suit was reported to dive to depth of 600 m. Despite diving 600 m, there is no perceptible movement of the joints. It is worth noting that the *Campos* joint set fail-safe design for the first time. If the joint failure happens, it can automatically seal and not let water into the suit, which has a great significance for the future design of ADS.

In 1917, German company Neufeldt & Kuhnke built two models of ADS based on the patent of ball-hole joint and used the ball to bear and transfer water pressure. In 1924, the German navy tested its second generation, diving to a depth of 161 m, which was very difficult to move the upper limbs and the joints had no fail-safe design (Scott 1931a). In 1931, with the help of this type of equipment, a total of 10 tons of silver COINS and 5 tons of gold COINS were recovered from a sinking ship in Egypt. Through this successful salvage, the suit gained a good reputation (Scott 1931b). In 1930, the suit was licensed to be built and sell. A developed type of *Galeazzi* with many

improvements to the original *Neufeldt & Kuhnke* was manufactured and sold more than 50 sets (Harris 1985).

In 1922, the British inventor Joseph Salim Peress applied for a spherical joint of oil filled and tried to make a type of ADS in 1925 but did not succeed. Then he developed the second type of ADS in 1932, named “*Tritonia*,” which is now often referred to as “*JIMI*.” There were only 8 ball joints, and equipped with simple tools (Barton 1973). *JIM I* was successfully used in *Lusitania*’s wreck salvage, with a maximum depth of 313 m. In 1937, it successfully completed the royal navy sea trial (Loftas 1973). The ball joint of this kind of ADS used hydraulic compensation for the first time, which laid a good foundation for the *JIM* used widely later. Early 1960s, a new type of *JIM* was designed, using the material of cast magnesium, which has high specific strength. See Fig. 2. The front of *JIM* is equipped with ballast, which allows the diver release in an emergency, then the *JIM* can rise to the surface at a speed of about 30 m per min. In 1971, the first set of *JIM* was carried

Atmospheric Diving Suit (ADS), Fig. 2 A JIM suit used by NOAA is recovered from the water. (Wikipedia, photo from NOAA)

out sea trials by the British naval ship *Reclaim*, and two divers arrived to the depth of 120 m. In 1981, the number of *JIM* has reached 19 sets (Earls et al. 1979), which is widely used in all kinds of underwater operations. *JIM* also became the basis of later developed ADSs.

The *WASP* was completed and put into use in 1978. It follows *JIM*'s design in many aspects but is designed as a GRP column below the waist to replace the lower body. The technology of propeller is adopted for the first time. It is equipped with a small multi-directional propeller, which is controlled by the pedal control board inside the cylinder, thus improving the maneuverability. A new generation of *WASP-III* put into production in 2001, to be able to descend to 760 m depth. The new *WASP* has a stronger vector propulsion system, lateral propulsion capability, and two camera systems.

Modern ADS

Phil Nuytten, developed the *NEWSUIT* based on the 1984 patent for rotating joints (Nuytten 1985), which is a truly somatological ADS. It has a wide range of activity allowing it to enter areas previously accessible only to divers. *NEWSUIT* is equipped with 16 patented hydraulic compensated rotary column joints that allow divers to drive the upper and lower limbs by themselves. The innovative joint greatly improves the working depth and flexibility of ADS and is a milestone in the history. The *NEWSUIT* life support system can guarantee 6–8 h of normal operation and 48 h of support in case of emergency.

In order to meet the needs of the army, the US navy cooperated with OceanWorks Company developed a series of *HARDSUIT1000* (305 m), *HARDSUIT1200* (365 m), and *HARDSUIT2000* (610 m) on the basis of *NEWSUIT*. See Fig. 3. The first two types adopt cast aluminum manufacturing, the other aluminum forging manufacturing. Meanwhile, *HARDSUITs* have become the standard equipment for French and Italian naval submarine rescue projects. In addition, the commercial model *HARDSUIT 2500* of *HARDSUIT 2000* will be applied in the industrial field, with a diving depth of 760 m.

Atmospheric Diving Suit (ADS), Fig. 3 U.S. Navy's ADS 2000 At the Ready. (Photo from OceanWorks Company)

Atmospheric Diving Suit (ADS), Fig. 4 QSZ-I atmospheric diving suit. (Photo from CSSRC)

China Ship Scientific Research Center (CSSRC) started research of ADS since 1980, and the first set of QSZ-I was developed in 1986. See Fig. 4. QSZ-I adopts spherical joints to connect limbs, and the maximum diving depth is 300 m. Sea trials with and without diver were carried out in the South China Sea. On the basis of QSZ-I, QSZ-II was improved in the 1990s. Four propellers were increased for depth control, height

control, and cruise control. The computer control system is improved to make divers' underwater activities more convenient and faster. Its biggest characteristic is that underwater movement has dual functions – it can choose to walk on the ground on the knuckles of the legs, and it can also rely on the power of the propeller to propel and cruise in the water. It can be controlled by the diver as well as the deck remote control. It is not only a manned submersible but also an unmanned observation submersible with remote control.

Since 2011, CSSRC began to develop a new type of ADS with the depth of 500 m, purposed to support marine oil and gas production safety maintenance and guarantee. The ADS has completed sea trials in 2015. The TMS, Launch and Recovery System (LARS), independent life support system, high-definition cameras, imaging sonar, two LED lights, emergency ballast, neutral line cutting, stroboscopic lamp, emergency pinger lamp, etc. equipped with the ADS forming a complete set.

After 2000, Phil Nuytten designed the latest *EXOSUIT*, which will work 305 m deep and reach 610 m in the future. The two salient features of the *EXOSUIT* are its lightweight and cable-free nature, allowing divers to swim within the *EXOSUIT* by swinging their lower limbs to drive their flippers, indicating that their joints are already highly flexible. It has 22 highly flexible rotary joints, and the foot swimming fins, the air (excluding divers) weighs only 72 kg. *EXOSUIT* has the ability of 48 h life support and is equipped with the latest underwater communications. It can be decomposed and loaded into a cylindrical vessel with a diameter of 0.4 m and a height of 0.6 m, which is convenient for storage in the submarine cabin. Traditional underwater operations, from compressed air to communication, rely on umbilical cables, so the effect of uncabled underwater operations needs to be further verified.

Principles of Modern Atmospheric Diving Suit

The arms and legs of modern ADS are connected by joints. The limbs are human-powered. Propulsion devices are equipped to maintain mobility in the water.

Joint is one of the key components of ADS. Hydraulic support column joint based on the patent of Phil Nuytten in 1984 is widely used now (Nuytten 1990). This type of joint has light weight, small rotation torque, large rotation angle, and reliable sealing. At present, the joint technical difficulties include: (1) underwater sealing technology – the research of sealing form and interior design parameters with high reliable seal and low rotating friction under deep water pressure; (2) rotary positioning technology – the research of rotary positioning between cylinder and piston with reliable radial and axial accuracy but not additional joint rotation torque and no appearance of stuck under high pressure; (3) hydraulic support technology – reliable design of hydraulic support to resist water pressure and reduce the rotational resistance under deep water pressure, also make sure that the joints can automatically compensate the amount of oil loss in the process of using; (4) pressure-resistant structure design – design of joints with lightest weight, most reasonable deformation control and uniform stress distribution meeting the requirements of working depth, and deformation under high pressure will not affect the sealing mechanism at the same time; (5) safety self-locking technique – when complete oil loss or sealing failure appears, the joints can lock themselves so as not to allow seawater to enter the cavity (Jiang et.al 2013a). It is a worldwide technical problem to develop high depth ADS that can meet the urgent requirements of high depth atmospheric diving suit.

The torso of ADS is somatological and the specific size is usually referred to ergonomic standards. Wrought aluminum milling forming is the popular process using at the time to ensure the density and intensity of the material. In addition, machining precision can be controlled strictly, make the thickness of the shell more reasonable, and the overall ADS weight lighter. There are four large openings in the upper body of the torso, including window opening, left and right upper limb opening, and waist opening, respectively. See Fig. 5. The same three openings in the lower body, respectively in the waist and the left and right lower limbs. It is necessary to carry out relevant theoretical analysis and experimental

Atmospheric Diving Suit (ADS), Fig. 5 The upper body of ADS torso with hemispherical viewing window. (Photo from CSSRC)

research on such non-regular, multi-channel, and large-opening structures. At present, the waist opening is usually adopted, which make divers in and out of ADS convenient. A bonus is the torso height can be adjusted by adding or removing torso sections to adapt to the needs of different height of the divers (Jiang et.al 2013b).

Hemispherical viewing window technology is also important. The *JIM* was originally designed with four viewing windows on the top. Later it was improved to a fully transparent Plexiglas helmet, providing a wider view for the operator. However, under the action of high pressure seawater, organic glass will undergo continuous creep deformation. This puts forward new requirements for design strength and safety. In addition, the manufacturing process of hemispherical viewing window is rather complicated. It is important to pay attention to the installation form of a hemispherical viewing window with torso connection. The study found that big bearing stress will occur during the progress of hemispherical glass shell inlaid into metal shell (Taylor and Lawson 2009).

Propellers are equipped on various types of ADS after the development of *JIM*, which are controlled by the pedal control board inside the ADS. Thus, the movement capability is

greatly improved. Two 2.25 hp constant speed adjustable pitch propellers are used on most existing ADS to help divers “fly” underwater or stay in the same site when they flow slightly down (Shen et al. 2015). The developing electronic ring propeller (ERP) is expected to reduce wear and maintenance and is the development direction of future propellers.

Neutral cable connects the ADS and TMS, transmitting the underwater power source, image information, status information and communication link between the diver and the deck commander (Liu 2009). When ADS is close to zero underwater buoyancy or a suspended state, the tensile force inside the neutral cable is very small, leading to several circle of cable looseness appears at the same time under fast cable releasing rapid. Therefore, the synchronous transmission mechanism consists of a set of counter-rotating active wheels and passive wheels will be necessary for cable smooth and orderly arrangement. The wheels provide the same direction traction to help send neutral cable out of TMS, while appropriate inverse hysteresis force to keep neutral cable tightly aligned back on the winch (Zhao et al. 2014).

Advantages

ADS is able to send divers directly to the underwater site, carrying out more effective operation. Smaller and lighter weight make it easier get into some limited space, engaging complex diving that only wet divers can do before. ADS eliminates or alleviates the physiological risks brought by ordinary wet diving. Divers do not need to decompress or pressurize for a long time, thus extending the underwater residence time and improving the operating efficiency. ADS can be equipped with various operation tools and adjust operation depth above rated work depth by propeller. When hovering over the water, ADS also has the ability of resistance to the current at the same time. With these advantages, ADS has a good military and civilian generality, increasingly wide application in all kinds of underwater operation, and it is gradually forming industry market. The advantages of low economic cost, high efficiency, and sufficient security also gradually revealed.

Key Applications

Application range of Atmospheric Diving Suit

ADS has become an effective way of underwater operation. In ocean engineering, ADS is currently used in deep-sea oil and gas resources development, realizing many functions such as offshore platform jacket installation, pipeline and cable laying, oil facilities and structure inspection support, underwater platform cleaning, rope hanging, life support POD delivering, and so on. It can also be used in offshore industries, such as underwater industrial operations. In the aspect of submarine rescue, ADS has successfully participated in the Deep Submergence Rescue Program of various countries and carried out the task of underwater rapid assessment and rescue. ADS can be widely used in the exploitation, operation, and application of deep-sea resources.

Important Events of Atmospheric Diving Suit

In 1975, the *JIM* won the privilege of petroleum engineering maintenance, carrying out oil well operations for 5 h 59 min at a depth of 300 m under water. *JIM* created the longest diving record in 150 m+depth work at the time (Curley and Bachrach 1982).

The *WASP* completed the repair of an oil pipeline 20 cm in diameter at a depth of 650 m under water in conjunction with a Remote Operated Vehicle (ROV), setting a record for the depth of the submarine pipeline maintenance work at that time (McCabe et al. 2000).

At the beginning of 1988, the *QSZ-I* conducted a 2500 square meters census of Yingxiu bay reservoir in Aba Tibetan autonomous prefecture, Sichuan province, inspecting concrete erosion and damage. In less than 10 days, the position of more than 2000 m² of underwater scouring, grinding, and silting was basically found out, which provided a technical basis for the reinforcement of the bottom plate of the dam gate of Yingxiu bay reservoir (Lin et al. 1990).

In the summer of 1988, the *QSZ-I* conducted dam crack detection for Beijing Zhuwo reservoir, scanning and recording five dam sections. According to the accurately specified position, underwater repair was successfully carried out.

The *NEWTsuit* first participated in the rescue of the wrecked ship *SS Edmund Fitzgerald* in 1995 (Jiang et al. 2013a).

In September 1998, the OceanWorks Company (OWC) completed a 2000-foot-deep manned submersible test for ADS2000 system in NEDU, Panama City. After several times of function demonstration experiments, ADS2000 system was officially delivered to the US navy (Gibson and English 2000).

Definition

Autonomous underwater vehicles (AUVs) are unmanned underwater vehicles (UUVs) without tethers that are powered by onboard energy sources. They are intended to accomplish predefined tasks with little or no human supervision. They can be fully or largely autonomous, communicating intermittently with operators using acoustic or radio links.

Gliders form a distinct subclass of AUVs. They move through the water column, translating the vertical forces of positive or negative buoyancy into a horizontal motion using wings. Whereas propeller-driven AUVs have endurance measured in hours or days (tens or hundreds of miles), glider endurance is measured in weeks or months (thousands of miles).

Brief History of AUV Development

AUV development began in the late 1950s (Blidberg 2001; Von Alt 2003). A few AUVs were built mostly to focus on data gathering. SPURV I (Widditsch 1973), the first “true” AUV developed by the Applied Physics Laboratory (APL) of the University of Washington in the early 1960s, displaced 480 kg and could operate at 2.2 m/s for 5.5 hours at depths to 3000 m. It was acoustically controlled from the surface and could autonomously run at a constant depth, seesaw between two depths, or climb and dive at up to 50°.

During the 1970s, a number of test beds were developed. The University of Washington (APL) developed the Unmanned Arctic Research Submersible (UARS) (Francois and Nodland 1972) and SPURV II (Nodland et al. 1981) (modified from SPURV I) to gather data from the Arctic regions. IFREMER’s Epulard was designed in 1976, assembled by 1978, and fully operational by 1980. Epulard was capable of diving to 6,000 m water depth and was operated remotely by an acoustic link. Also at this time, the development of the SKAT vehicles started under the AUV program of Institute of Marine Technology Problems, Russian Academy of Sciences.

In the 1980s a number of technological advances greatly affected AUV development. Small, low-power computers and memory offered the potential of implementing complex navigation and control algorithms on autonomous platforms. Advances in software systems and engineering made it possible to develop complex software systems. The Advanced Unmanned Search System (AUSS), developed by the Naval Oceans System Center (now SPAWAR) of the United States, was launched in 1983. AUSS displaced 907 kg, carried 20 kw hours of energy in silver-zinc batteries, and was rated to 6000 m. It had an acoustic communication system that transmitted video images through the water.

During 1990–2000, AUVs grew from proof-of-concept test beds into operational systems able to accomplish specified tasks. A number of organizations around the world undertook development efforts focused on various operational tasks. Examples include Odyssey of MIT Sea Grant AUV Lab, Autonomous Benthic Explorer (ABE) and REMUS of Woods Hole Oceanographic Institution (WHOI) (Yoerger et al. 1991; Allen et al. 1997), Autosub of Southampton Oceanographic Centre (Brierley et al. 2002), The-seus of International Submarine Engineering (Butler and den Hertog 1993), and Hugin of Kongsberg Simrad of Norway (Storkersen et al. 1998).

Since 2000, AUV technology extended from the academic and research environment into the commercial mainstream of the ocean industry. Examples include Nereus (Bowen et al. 2008; Bowen et al. 2009) and Sentry (Yoerger et al. 2006) of WHOI, Bluefin of (Panish et al. 2011), r2D4 of the University of Tokyo (Ura et al. 2004), Tethys long-range AUV of Monterey Bay Aquarium Research Institute (MBARI) (Hobson et al. 2012).

AUV Subsystems and Technologies

Pressure and Hydrodynamic Hulls

By providing enclosed chambers for the onboard equipment that needs to work in dry, atmospheric environment, pressure hulls withstand the

ambient pressure. As the depth rating increases, the proportion of vehicle weight allocated to pressure hull increases, thus reducing the proportion of weight allocated to the other systems including energy source.

Depending on depth ratings, pressure hulls can have either cylindrical or spherical shapes. The most common materials for pressure hulls are aluminum or titanium. However, the use of ceramics as a pressure hull material appears promising and has been verified in WHOI Nereus (Bowen et al. 2008).

Hydrodynamic hulls are intended to reduce flow drag as AUVs move through water to maximize speed and endurance. Streamlined hulls are preferable as they generate less turbulent flows around vehicle body. However, the hydrodynamic performance of the laminar flow body degrades significantly when the hull shape is changed due to mission configuration. Therefore, torpedo body that has a nose cap followed by a parallel midsection and a tapered tail section is applied as an alternative and thus leads to an additional drag of approximately 30%.

Ballast

Although traditional AUVs are designed to have slightly positive buoyancy and passive stability (the ability to return to the upright position), it is still desirable to adopt ballast to aid ascent and descent. Emergency drop weights, also part of ballast systems, are released in the event of hardware failure so that the vehicle returns to the surface.

Energy and Power Management

Most power systems for AUVs rely on batteries that supply limited energy. Lead-acid batteries became common AUV power sources in the 1980s. However, such batteries provide relatively little energy given their weight. Silver-zinc batteries replaced lead-acid batteries but proved expensive and vulnerable to failure after relatively few cycles. Alternatively, vehicles have used lithium primary batteries, which are not rechargeable. With advance in the development of more efficient and safer batteries for electric cars, the rechargeable lithium-ion battery has been widely used as energy source for current AUVs.

A number of battery cells are connected in series to form battery banks which are then connected in parallel to provide sufficient current draw by onboard electrical devices. To ensure uniform battery drain and to handle ground faults, power management system is needed. Power management system monitors the main bus voltage and the current drawn from each battery bank. Based on this data, the energy used is calculated and the energy remaining can be estimated.

Propulsion and Maneuvering Systems

Propulsion for torpedolike AUVs is generally provided by electric motors that drive propellers. As the amount of energy AUVs that can carry onboard is limited, the efficiency of the propulsion system is critical to minimize the amount of electrical power consumed. Due to their advantages over brushed motors in efficiency, reliability, and power density, brushless direct-current (DC) motors are applied increasingly for AUV propulsion systems. For a propulsion system to achieve high efficiency, it may be necessary to match the optimal rotational speeds of motors and propellers by reduction gears. Transmission loss needs to be considered as well.

Most AUVs maneuver by deflecting control surfaces or vectored propulsors. In missions that require hovering, vehicles can maneuver to face against currents. Alternatively, multiple thrusters can be applied to allow vehicles to hover with demanded heading. Gliders can maneuver by shifting weights along longitudinal axes for pitching and rotating weight (such as batteries) around longitudinal axes for rolling and yawing. To achieve desirable sawtooth pattern, changing buoyancy and shifting internal weights have to be coordinated.

Navigation and Positioning Systems

Navigation and positioning systems, on their own, reckon AUVs' positions from various types of motion sensors by fusion algorithms, e.g., Kalman filter or particle filters (Stutters et al. 2008). Positional information is the indispensable part of the survey data collected by AUVs. By working together with control systems, navigation and positioning systems enable AUVs to move along

pre-defined tracks which are specified by path/trajectory (motion) planners.

For low-cost AUVs, primary onboard motion sensors include global positioning system (GPS) receiver (valid only when AUVs are on surface), strap-down microelectromechanical systems (MEMS), inertial navigation system (INS), depth sensor, and magnetic compass. INS integrates acceleration and angular rate from inertial measurement unit (IMU) to estimate motion states, which include translational and rotational speeds, position, attitude, and heading. Magnetic compass determines vehicle's heading relative to the north direction. Depth sensor measures vehicle's depth in terms of the ambient hydrostatic pressure.

To reduce the growing rate of error in position estimate, MEMS-based INS is replaced by fiber optic gyro (FOG)- or ring laser gyro (RLG)-based INS. Moreover, Doppler velocity log (DVL) that transmits four separate beams downward from the vehicle to measure the speed relative to the bottom is required (Kinsey and Whitcomb 2004).

Even equipped with FOG-/RLG-based INS and DVL, the positional error involved in navigation and positioning system grows with time. For some missions, external position fixes are usually needed to assist navigation and positioning system. Underwater position fixes are often provided by acoustic positioning systems, e.g., ultrashort baseline (USBL) system and long baseline (LBL) systems. With only one transducer installed on the ship hull, USBL is portable and consequently preferred when a variety of surface ships may be used. However, careful shipboard calibration is required to provide adequate positional accuracy. Traditional LBL requires both the deployment of equipment on the seafloor and careful calibration. Inverted LBL, where GPS receivers are used on the ocean surface, is promising as shipboard calibration is not required.

Control Systems

Generally, control systems can be divided into motion and equipment control systems. While the latter mainly deals with control of onboard devices, e.g., switching of power for equipment and payload sensors, the former enables the

vehicle to move with demanded pattern that matches the pre-defined tasks.

From the viewpoint of implementation, equipment control is not difficult as simple logic-based algorithms are sufficient. However, motion control is a challenge as both complex vehicle dynamics and various disturbances have to be dealt with (Yuh 2000).

As roll and pitch modes are often left uncontrolled due to their passive stability, primary motion control system enables AUVs to move with demanded forward speed, heading, and depth. Advanced motion control system requires AUVs to move along pre-defined tracks with specified forward speed, heading, and depth.

With motion controller as its "brain," motion control system generates maneuvering commands for propulsion and maneuvering system, which in turn drive thrusters and/or control surfaces, in terms of the deviation between the set and feedback values of interested motion states, e.g., forward speed, heading, and depth.

It is the motion controller that needs to deal with the complex vehicle dynamics and various disturbances. Dynamics of underwater vehicles, including hydrodynamic parameter uncertainties, are highly nonlinear, coupled, and time varying. Disturbances come from ocean currents, varying buoyancy due to the density variation of seawater at different depths and near-surface wave-suction forces. Typical control schemes include sliding mode control (Yoerger and Slotine 1985; Healey and Lienard 1993), nonlinear control (Nakamura and Savant 1992), and adaptive control (Zhao et al. 2004).

Communications

Bidirectional acoustic, radio-frequency, and satellite-based communications systems enable human operators to supervise and redirect AUV missions from a ship or from land. However, the duty cycle of the telemetry system can have a significant impact on AUV energy requirements or endurance.

Compared to radio-frequency communications, high-speed communications in the underwater acoustic channel has been more challenging because of limited bandwidth, extended

multipath, severe fading, rapid time variation and Doppler shifts (Chitre et al. 2008). While robust low-complexity incoherent techniques for low data rate acoustic communications have been employed widely, coherent techniques are promising.

Motion Planning

To a great extent, the autonomy of AUVs is equivalent to their ability of motion planning, that is, generating collision-free, dynamically feasible, and low-cost trajectories which enable AUVs to accomplish their missions.

Path planner is the essential part of a motion planner. Traditional path planner often imposes a discretization over the operational area and searches an optimal path over the discretization. The discretization is obtained by imposing a regular grid represent the collision-free areas. Since vehicle dynamics is not taken into account, the planned paths are not necessarily dynamically feasible (Button et al. 2009).

Therefore, it is desirable for AUVs to plan their trajectories online in response to vehicle motion states while deliberating on how best to follow the paths planned in advance. In addition, motion planners will have to reason about the high-level aspects that are related to the dynamic interaction between AUVs and their surroundings. There is a growing need to reason about both the high-level and low-level aspects simultaneously (McMahon and Plaku 2016).

Payloads

Payloads on-board AUVs mainly include acoustic, magnetic, electromagnetic, optical, and CTD (conductivity, temperature, and depth) sensors. Mounted on AUVs that move near the bottom with constant altitudes, the data connected by these payload sensors have higher and more consistent spatial resolution than their shipboard compartments.

Acoustic Sensor

Typical acoustic sensors include multi-beam sonar, side-scan sonar, and sub-bottom profiler.

Multi-beam sonars consist of a Mills Cross transducer array that produces multiple across-

track beams as the intersection of one transmit beam (fan shaped across the survey track) with numerous receive beams (each fan shaped along the track). This allows the sounder to provide continuous swath bathymetry over a 120–150° sector.

Side-scan sonars are one of the most accurate sensors for imaging large areas of the ocean floor by transmitting beams of acoustic energy from the sides of the vehicle (across the track). Unlike a ship, the sonar transducers of side-scan sonar are mounted on the vehicle hull rather than towed.

Sub-bottom profilers are a shallow geophysical sonar designed to provide higher-resolution profiles below the seabed but with less penetration than lower-frequency seismic equipment such as air guns and sparkers. Sub-bottom profiler images are made up of backscatter from the seafloor strata. The first boundary is at the seabed, between the water and the seafloor itself. As layers of clay, sand, and various other sediments succeed each other, they reflect sound at their interfaces. It is this reflected energy that the system uses to build the image.

A recent trend in active sonars is synthetic aperture sonar (SAS). Whereas simple active sonars emit individual pings and process them individually, SAS systems on moving AUVs assemble images from multiple pings and thus give sonar designers the means to increase sonar aperture and improve resolution by an order of magnitude.

Magnetic Sensor

Magnetic sensors include magnetic compass and magnetometer. While the former is used for AUV navigation (heading), the latter is applicable to inspect pipelines/cables and to locate ferrous objects on the seabed.

Optical Sensor

Imaging optical sensors include still and video cameras augmented by lighting systems. The performance of imaging optical sensors for missions such as inspection can also be enhanced using simple dual-laser scaling devices that emit parallel beams of light separated by a known distance.

Pairs of dots projected by these devices provide a scale helpful in visually identifying objects.

Non-imaging optical sensors are used for basic tasks, such as measuring water turbidity.

CTD Sensor

CTD sensors are used to collect oceanographic data and predict and improve the performance of onboard sonars. The conductivity of seawater is closely linked to its salinity. Salinity, temperature, and depth are, in turn, the predominant factors used to predict undersea sound velocity. Therefore, CTD sensors can be thought of as calibrating tools for the active sonars.

Key Applications

With advances in AUV technologies, e.g., high-density energy source, underwater navigation and communication, and sensing, AUVs have been increasingly applied in ocean exploration and exploitation. Most AUVs have been developed to accomplish science, commercial, and military missions.

Science Mission

Typical science missions include:

- Locating, mapping, and photographing hydrothermal vents by WHOI ABE (German et al. 2008).
- High-quality acoustic imaging of seabed by the University of Tokyo r2D4 (Ura et al. 2004).
- Conducting swath sonar measurements under sea ice by the University of Southampton Autosub II (Wadhams et al. 2006).
- Tracking a coastal upwelling front by MBARI's Tethys long-range AUV (Zhang et al. 2012).
- Capturing water samples at chlorophyll fluorescence peaks in a thin phytoplankton layer by MBARI dorado (Zhang et al. 2010).
- Assessing the Deepwater horizon oil spill with WHOI's sentry (Kinsey et al. 2011)
- Oceanographic research with commercial gliders Seaglider (Eriksen et al. 2001), Slocum (Webb et al. 2001), and spray (Sherman et al. 2001).

Commercial Mission

Typical commercial missions include:

- Survey of gas transport pipeline route with Kongsberg Hugin 1000 (Marthiniussen et al. 2004)
- Offshore surveying with Kongsberg Hugin 3000 (Marthiniussen et al. 2004)
- Undersea-cable deployment and inspection with ISE Theseus (Butler and den Hertog 1993)
- Searching wreckages of missing airplanes, e.g., REMUS 6000 for Air France Flight 447 and Bluefin-21 for Malaysia Airlines Flight 370

Military Mission

Typical military mission includes autonomous mine reconnaissance survey with Kongsberg Hugin (Marthiniussen et al. 2004).

Definition

Control system is a kind of active regulation system designed to improve or optimize specific performance or indicators for economic, social, or physical systems. AUV/ROV/HOV belongs to a multi-degree-of-freedom underwater platform system with high redundancy, coupling, and

model nonlinearity. It works underactuated in complex underwater environment, and the body must maintain autonomous stability in the process of operation. Therefore, the design of appropriate control system to ensure the stability of the underwater platform during the operational process is of great significance to the successful and accurate completion of the underwater mission of AUV/ROV/HOV.

Scientific Fundamentals

Difficulties in the Design of Control System

Underwater vehicles have a large variety of types, and they are widely involved in undersea surveillance, inspection, and survey missions. Typically, gliders are common with a torpedo shape for long range missions, and human-occupied vehicles (HOVs) as well as remote operating vehicles (ROVs) are generally of a cubic shape used for hovering tasks. For some specific applications, undersea pipeline inspection, offshore infrastructure surveillance, and large vessel maintenance, AUV is preferred.

Regardless of modeling issues, the value of a model-based control approach depends on how robust and efficient the control scheme can adopt the hydrodynamic model. Potential trends of current methods focus on faster controllers to assist the pilot or the autopilot with better accuracy. Optimal controllers can reduce propelling actions to save the battery power as well as to increase the propeller lifespan. Moreover, numerous uncertainties should be considered, including parameter variations, nonlinear hydrodynamic damping effects, sensor transmit delays, and ocean current disturbances (Clement et al. 2016).

Each underwater vehicle is designed to perform specific functions. Even for the same type of underwater vehicle, their shapes may be very different. Therefore, the mathematical models of underwater vehicles will be much different. Each underwater vehicle pursues unique performance indicators. This makes it difficult to solve all control system design problems with a single theory or model system.

A decade of operational experience by numerous research groups has demonstrated ROVs to be ideal platforms for “rapid prototyping” and “rapid field deployment” of UUV subsystems. Recent examples include sonar imaging and survey, optical imaging and survey, navigation, control, oceanographic sampling, and subsea manipulation. Numerous research results first pioneered with ROVs, and towed vehicles are now commonly employed for autonomous underwater vehicles (AUV, HOV) and seafloor observatories (Smallwood et al. 1999).

Structure of Underwater Vehicle System

In the following chapters, the typical structure of the underwater vehicle system will be given. These components are the integral part for underwater vehicle to complete basal motion.

The submersible control system has two components, surface ship control system and underwater vehicle control system. The surface ship control system includes system GMT clock, ship dynamic positioning system, ship LBL navigation system, GPS satellite navigation system, real-time data logging system, science payload interface, instruments, video distribution, and recording subsystem. The underwater vehicle control system includes vehicle control computer system, surface telemetry, pilot’s user interface (such as joystick, keyboard instruction), engineer user interface, manipulator user interface, work package interface, and pilot video display. Vehicle control computer system includes control process, positioning navigation process, LBL-Doppler navigation process, and power management and hotel process, shown in Fig. 1.

Surface Systems

The surface control system is the central “brain” of the ROV control system. It is comprised of a “core” system of safety-critical systems that are essential for safety and control of the ROV and an “extended” system providing non-safety-critical systems such as data logging and video recording. The safety-critical core system is comprised of the vehicle control computer and user interfaces for the vehicle pilot and engineer. The pilot station provides real-time video and navigation

instruments, has joystick controls for closed-loop control of the vehicle reference trajectories and navigation waypoints, and has controls for the vehicle’s manipulator arms. The engineer station has a more comprehensive set of real-time vehicle status indicators and enables the engineer to control all vehicle subsystems. The modules are depicted in Fig. 1.

Concentrating the vehicle intelligence in the ship-board control computer dramatically simplifies and accelerates development – reprogramming an on-ship computer is significantly easier than reprogramming an embedded vehicle control computer.

Vehicle on-Board Core Control System

The on-board vehicle control system controls and monitors all vehicle sensors and actuators in response to real-time commands from a surface control system. We will adopt a “data concentrator” (DCON) type of architecture. Each data concentrator (DCON) module will independently control the power and data telemetry for an entire vehicle subsystem or scientific payload. The DCONs will receive commands from the surface control computer, monitor the status, and report data from on-board vehicle subsystems and instruments. Each data concentrator operates asynchronously and will communicate to the surface control computer via a high bandwidth fiber-optic telemetry link.

The data concentrator vehicle control system architecture employs relatively simple on-vehicle computer systems. We anticipate employing commercial off-the-shelf (COTS) embedded computers for the data concentrators. The simplicity of the data concentrator design will render them both highly reliable and easily reconfigurable (Smallwood et al. 1999).

Realization of Vehicle Control System

Generally, the underwater vehicle is equipped with scanning sonars and a color CCD camera, together with depth sensors and a fiber-optic gyroscope. This device is intended primarily as a research platform upon which to test novel

AUV/ROV/HOV Control Systems, Fig. 1 Underwater vehicle system structure (Smallwood et al. 1999)

sensing strategies and control methods. Autonomous navigation using the information provided by the vehicle's on-board sensors represents one of the ultimate goals of the project (Williams et al. 2006).

Embedded Controller

At the heart of the robot control system is an embedded controller. Figure 2 shows a schematic

diagram of the vehicle sensors and their connections. The vehicle uses a CompactPCI system running Windows CE that interfaces directly to the hardware and is used to control the motion of the robot and to acquire sensor data. While the Windows operating system doesn't support hard real-time performance, it is suitable for soft real-time applications, and the wide range of development and debugging tools make it an ideal

AUV/ROV/HOV Control Systems, Fig. 2 Vehicle control system diagram system (Williams et al. 2006)

environment in which to test new navigation algorithms. Time-critical operations, such as sampling of the analog to digital converters, are performed on the hardware devices themselves and use manufacturer-supplied device drivers to transfer the data to the appropriate processes.

The sensor data is collated and sent to the surface using an Ethernet connection where a network of computers are used for further data processing and data logging and to provide the user with feedback about the state of the sub. Communications between the computers at the surface and the sub are via a tether. This tether also provides power to the robot, a coaxial cable for transmitting video data, and a leak detection circuit designed to shut off power to the vehicle in case of a leak. While some effort might have been spent on eliminating the tether, it was felt that the development of the navigational techniques was of more immediate interest.

Sonar

Sonar is the primary sensor of interest on the vehicle. There are currently two sonars on the robot. A sonar unit has been mounted at the front of the vehicle. It is positioned such that its scanning head can be used as a forward and downward looking beam. This enables the altitude above the seafloor as well as the proximity of

obstacles to be determined using the wide of the angle beam of the sonar.

The second sonar is an imaging sonar and has a dual frequency narrow beam sonar head that is mounted on top of the sub and is used to scan the environment in which the sub is operating. It can achieve 360° scan rates on the order of 0.25 Hz. The information returned from this sonar is used to build and maintain a feature map of the environment.

Internal Sensors

A laser Gyro has been included in the robot to allow the robot's orientation to be determined. This sensor provides yaw rate information and is used to control the heading of the sub. We currently estimate the bias in the gyroscope reading prior to a mission. The bias compensated yaw rate is then integrated to provide an estimate of vehicle heading. Because the yaw rate signal will inevitably be noisy, the integration of this signal will cause the estimated heading to drift with time. At present, missions do not typically run for longer than 30 minutes, and yaw drift does not pose a significant problem on this time frame. In the future, a compass will be added to the system to allow us to periodically reset the heading for longer missions. This will also allow us to detect changes in the yaw rate bias that typically

occur as a result of changes in the internal temperature of the unit.

A pressure sensor measures the external pressure experienced by the vehicle. This sensor provides a voltage signal proportional to the pressure and is sampled by an analogue to digital converter on the embedded controller. The pressure can then be converted to a depth below the surface of the ocean. Feedback from this sensor is used to control the depth of the sub.

Camera

A Panasonic camera in an underwater housing is mounted externally on the vehicle. It is used to provide video feedback of the underwater scenes in which the robot operates. This is a color camera and sends the video signal to the surface via the tether. A video acquisition card is then used to acquire the video signal for further image processing.

Thrusters

There are currently six thrusters on the vehicle. Four of these are oriented in the vertical direction, while the remaining two are directed horizontally. This gives the vehicle the ability to move itself up and down, control its yaw, pitch and roll and move forward and backward, and move lateral motion.

Vehicle Control Method

Control system of a mobile robot in six-dimensional space in an unstructured, dynamic environment that is found underwater can be a daunting and computationally intensive endeavor. Navigation and control both present difficult challenges in the subsea domain. We have developed a distributed, decoupled control architecture to help simplify the controller design.

The vehicle control architecture currently running on the sub is based on the Distributed Architecture for Mobile Navigation (DAMN) as proposed in Rosenblatt (1997). This behavior-based control architecture uses a centralized arbiter to combine votes from various behaviors running in the system in order to determine the optimal course of action to pursue. A behavior

encapsulates the perception, planning, and task execution capabilities necessary to achieve one specific aspect of robot control and receives only that data specifically required for that task (Brooks 1986).

Decoupled Control

By decoupling the control problem, individual controller design is greatly simplified. In the case of the typical vehicle, vertical motion is controlled independently of its lateral motion using two separate PID controllers. These controllers are then tuned to provide the required performance in each case.

This division of control has been selected as it fits in with many of the anticipated missions to be undertaken by the vehicle. A typical mission might see the vehicle performing a survey of an area of the Great Barrier Reef while maintaining a fixed height above the seafloor (Williams et al. 1999). The task of performing the survey can then be made independent of maintaining the vehicle altitude. This also allows us to optimize the performance of the depth controller prior to deploying the navigation algorithms used for mapping of the environment to ensure that the vehicle has little risk of hitting the sea floor.

The behaviors that run on the vehicle are also divided into horizontal and vertical behaviors, and there are consequently two arbiters currently present. One is responsible for setting the desired depth of the vehicle, while the other sets the desired yaw and forward offset to achieve horizontal motion.

For a survey mission, the vertical behaviors would typically be responsible for keeping the sub from colliding with the seafloor. The vertical behaviors that run on the vehicle include maintain minimum depth, maintain minimum altitude, maintain depth, and maintain altitude. The combination of the outputs of these behaviors determines the depth at which the vehicle will operate. A large negative vote by the maintain minimum altitude behavior will keep the vehicle at a minimum distance from the seafloor. The horizontal behaviors that would run on a survey mission include follow line (sonar and/or vision), avoid

obstacles, move to location, and perform survey. The combination of the outputs of these behaviors determines the orientation maintained by the vehicle as well as the forward offset applied to the two horizontal thrusters. This allows the vehicle to move forward while maintaining its heading.

Low- and High-Level Control

The control of the sub is further decoupled into low level- and high-level control processes. The low-level processes run on the embedded controller and are used to interface directly with the hardware (see Fig. 3). In addition, the PID controllers have been implemented at this level. This allows the PID controllers to respond quickly to changes in the state of the sub without being affected by the data processing and high-level control algorithms running at the surface.

The high-level processes run on a pair of Pentium machines at the surface control station. Information from the sub's sensors is fed to a series of processes running on these machines. These processes use the data supplied by the sensors to determine the desired set points for the low-level control processes. The raw sensor data is preprocessed to produce virtual sensor information – information that is of interest to multiple behaviors in the system. The behaviors register their interest in the data being generated by the virtual sensors and send votes to the arbiters to specify their desired course of action. A task-level mission planner is used to enable and disable behaviors in the system depending on the current state of the mission and its desired objectives. The arbiter combines the votes from the behaviors and selects the optimal action to satisfy the goals of the

AUV/ROV/HOV Control Systems, Fig. 3 The low-level control processes that run on the vehicle controller. These processes include processes for sampling the internal

sensor readings, computing the PID control outputs, and driving the thrusters (Williams et al. 2006)

system. A schematic representation of the data flow within the system is shown in Fig. 4. This control strategy relies on the ability of the sub to gather information about its environment and reason about its desired actions. By continuously monitoring the state of the environment, the sub is able to respond to changes as they occur.

Distributed Control

A number of processes have been developed to accomplish the tasks of gathering data from the robot's sensors, processing this data, and reasoning about the course of action to be taken by the robot. These processes are distributed across a network of computers and communicate asynchronously via a TCP/IP socket-based interface using a message passing protocol developed at the center.

A central communications hub is responsible for routing messages between the distributed processes running on the vehicle and on the command station. Processes register their interest in messages being sent by other processes in the system, and the hub routes the messages when they arrive. While this communications structure has some drawbacks, such as potential communications bottlenecks and reliance on the performance of the central hub, it does provide some interesting possibilities for flexible configuration, especially during the development cycle of the system.

The above introduction mostly comes from Smallwood et al. (1999) and Williams (2006). More technical details or design method can be found in their related literature.

Key Applications

Over the past 20 years, with the widespread development of large-scale integrated circuit in the world, which plays an important role in the field of marine technology, many new submarine vehicles have been created to solve a wide range of problems. These devices have already demonstrated their effectiveness in performing emergency rescue, ocean survey, environment monitoring, inspections and operation, research, and other types of work.

Because the marine environment is unstructured and hazardous, the development of underwater vehicles will face many challenging scientific and engineering problems, and researchers have made great efforts to overcome these problems so far (Paull et al. 2014). The progress in new materials, sensor technology, computer technology, and advanced algorithms has greatly contributed to research and development activities in the underwater vehicle community.

With technological advances, underwater vehicles have the advanced control technology and intelligent control system that can efficiently perform scheduled tasks with its own decision-making and control capabilities.

Advanced Control Technology

The AUV control methodologies that have been proposed in the literature include linear control (see Yildiz et al. (2009)), sliding mode control (see Yang et al. (2013) and Kim et al. (2015)), and fuzzy and neural network control (see Khodayari and Balochian (2015) and Lakhekar et al. (2015)).

One simple and effective nonlinear control design approach that has been implemented in marine applications is dynamic inversion (DI), in which the control law is formulated to eliminate system nonlinearities by means of feedback. The DI control technique in turn allows to incorporate well-established linear control techniques. In spite of its flexibility and simplicity, standard DI lacks robustness to model uncertainties. Several modifications were added to the basic DI control structure to improve its robustness characteristics; see Steinicke and Michalka (2002) and Wang et al. (2012). Regardless of these attributes, DI has several shortcomings and limitations, including blind nonlinearity cancellation, large control effort, and numerical singularity configurations of square matrix inversion.

A new inversion-based control design methodology is Generalized Dynamic Inversion (GDI); see and Bajodah (2009). The methodology is of the left inversion type, and hence it does not involve deriving inverse equations of motion for the plant. In GDI, dynamic constraints are prescribed in the form of differential equation that encapsulates the control objective and is

AUV/ROV/HOV Control Systems, Fig. 4 The high-level process and behaviors that run the vehicle. The sensor data is preprocessed to produce virtual sensor information available to the behaviors. The behaviors receive the virtual sensor information and send votes to the arbiters who send control signals to the low-level controllers (Williams et al. 2006)

generalized inverted using the Moore-Penrose Generalized Inverse (MPGI)-based Greville formula. The GDI control technique has been an effective tool for several engineering problems; see Bajodah (2009), Bajodah (2010), Hameduddin and Bajodah (2012), and Gui et al. (2013). The Robust Generalized Dynamic Inversion (RGDI) control system is obtained by Ansari and Bajodah (2017).

Location and Navigation Technology

Navigation is one of the key AUV technologies because the localization, path tracking, and control of the vehicle are all based on precise navigation parameters. Some navigation methods commonly used for land and air are not suitable for underwater because of the attenuation effect of water on electromagnetic signals, and underwater navigation has become a challenging issue in AUV research (Paull et al. 2014). Among the many underwater navigation systems available, the inertial navigation system (INS) using inertial sensors typically acts as the central navigation system of AUVs because of its autonomy (Stutters et al. 2008).

Generally, the INS contains an inertial measurement unit (IMU), which consists of accelerometers measuring linear acceleration and gyroscopes measuring angular velocity; the

accelerometers and the gyroscopes are usually made up of three mutually perpendicular accelerometers and three mutually perpendicular gyroscopes, respectively. For inertial navigation, the instantaneous speed and position of the vehicle are obtained by integrating the measured values of the accelerometers and gyroscopes. The errors of the IMU increase with increasing elapsed time due to the drift of accelerometers and gyroscopes. Theoretically, the velocity and heading errors accumulate linearly over time, and the position error accumulates exponentially over time (Ali and Mirza 2010). Therefore, the INS can provide relatively accurate navigation information within a short time, but it is physically impossible for a pure inertial navigation system to maintain the high-precision level throughout a mission. Aiding the INS with external information or measurements is an effective means of improving navigation accuracy and has been widely used. In AUV navigation, auxiliary sensors or other navigation systems, such as a Doppler Velocity Log (DVL), compass, pressure sensor, Global Positioning System (GPS), acoustic positioning system (APS), or geophysical navigation system, are usually combined with the INS to form an integrated navigation system (Kussat et al. 2005 and Vasilijevic et al. 2012) (Figs. 5 and 6).

AUV/ROV/HOV Control Systems, Fig. 5 SINS/DVL integrated navigation structure (Bao et al. 2019)

AUV/ROV/HOV Control Systems, Fig. 6 Principle diagram of geophysical navigation-assisted inertial navigation (Bao et al. 2019)

AUVs typically use the INS as their main navigation system; however, due to inherent error accumulation of inertial sensors over time, the pure INS has difficulty obtaining long-range precision navigation. Therefore, INS is often combined with other navigation systems or devices such as GPS, DVL, acoustic positioning systems, or geophysical navigation systems to improve the AUV navigation accuracy (Bao et al. 2019).

Synonyms

Buoyancy; Density; Displacement volume; Fixed weight; Hydrostatics pressure; Salinity; Submerged depth; Temperature; Variable weight; Weight

Definition

Hydrostatics is a kind of ability to enable an AUV/ROV/HOV afloat in the certain diving depths. The relationship between buoyancy and weight results in two primary flotation conditions: surfaced and submerged. Variation in weight must be supported by the corresponding buoyancy for each condition. Many configurations, such as the suitable location of the main ballast tanks (MBTs), solid droppable ballast, and buoyancy material, may be adopted to control hydrostatics of submersibles for different purposes.

Scientific Fundamentals

As with any object in a fluid, a submerged AUV/ROV/HOV must conform to Archimedes Principle, which is applied on by two opposite direction forces: upward buoyancy (due to the displacement of water by its hull) and downward weight (Renilson 2015). The AUV/ROV/HOV is sensitive to variation in both buoyancy and weight. An exact equality of these two forces is termed “neutral” buoyancy, which is a hover condition (to keep a given depth while stationary); if weight exceeds buoyancy, known as “negative” buoyancy, the submersible will drop and deeply submerge to the seabed. Conversely, if buoyancy exceeds weight, known as “positive” buoyancy, the submersible will rise to float on the water surface (Burcher and Rydill 1994).

An AUV/ROV/HOV on the surface has to satisfy the same hydrostatic principles. However, it has a smaller watertight volume above water and relatively lower water-plane characteristics than that of a surface ship. With the flooding water into the ballast tanks, the weight of AUV/ROV/HOV increases and the submersible transitions from floating on the surface to being fully submerged. Correspondingly, the immersed volume, termed “displacement,” is also enlarged until the integral structure volume (maximization).

Buoyancy Force

The buoyancy force of submersible is given by the immersed volume, partly or fully, multiplied by the water density and gravity acceleration, i.e.,

$F = \rho gV$, where ρ is the density of seawater, g is the acceleration due to gravity, and V is the immersed volume of the submersible.

Hydrostatic Pressure

The force acting on the submerged AUV/ROV/HOV is the weight of the seawater column above it. Since seawater can be considered incompressible and the variation of g can be neglected (the height h of fluid column is much smaller than the radius of Earth), hydrostatic pressure can be calculated according to the following formula: $p - p_0 = \rho gH$, where p is the hydrostatic pressure, p_0 is the atmospheric pressure on sea surface, and H is the height from the surface to the submerged depth.

Displacement Volume

The changes in the geometry of the AUV/ROV/HOV will be caused by hydrostatic pressure loading with depth. The hydrostatic pressure is increased with the greater submerged depth, which results in a reduction in displacement volume. Therefore, the buoyancy will be reduced due to the compression as diving depth increases, especially for the deep submersible. On the other hand, as submerging, the temperature around the AUV/ROV/HOV is different, which has also an effect on the immersed volume, especially for the volume of solid buoyancy material. That is to say, the displacement volume is the function of hydrostatic pressure and the temperature (Tie dong 2010). The changes in displacement volume due to the variation in these two parameters result in different buoyancy subsequently.

Density

Buoyancy is not only dependent on the volume but also on the density of the water. And the density is varied if the AUV/ROV/HOV is operated in different areas. Seawater specific gravity (SG) can range from 1.00 near the mouths of rivers or in fjords where the water is virtually fresh due to melting glaciers, to about 1.03 where there is high salinity. A standard value of 1.0275 toward the higher end of the density range is averagely encountered in a submersible operation. When the AUV/ROV/

HOV approaches a coast or where there are substantial changes with depth (layers) of temperature and salinity, a quite large change may occur rapidly, and a variation of 3% in buoyancy due to seawater density variation would be adopted in the design (Burcher and Rydill 1994).

As well as salinity effecting to the density of displacing seawater around submersible, the hydrostatic pressure due to the submerged depth from the sea surface and the temperature also affect the density. With the increase of the submerged depth, hydrostatic pressure will be larger and the temperature will be lower. For the same salinity, the lower temperature results in a higher density of water; while for the same temperature, the higher salinity leads to higher density. Therefore, the density is determined by the salinity, the temperature, and the hydrostatic pressure. Then any changes of density will result in the variation of buoyancy.

Weight

The determination of the weight of an AUV/ROV/HOV is more complicated than that of buoyancy. Whereas buoyancy is primarily related to gross volumes of geometrically simple forms and the density of displacing water; weight is the summation of every element (fixed weight and variable weight) that goes into a submersible. The fixed weight consists of large components, such as pressure hull structure, main propulsion plant, batteries, etc., and some minor structures and systems, which are permanently installed components. The variable weight associates with crew, their effects, stores, and the fluid contents of many tanks.

TRIM

The mass and longitudinal center of gravity of a submersible will change during the operations. In addition, changes in seawater density and hull compressibility will all result in small changes to buoyancy and position of the center of buoyancy. Therefore, it cannot be kept in upright position any more, maybe in longitudinal inclination equilibrium because of these changes.

Key Applications

Unlike for a surface ship, in the case of a deeply submerged AUV/ROV/HOV, the immersed volume cannot be increased by increasing the vessel's draught. Thus, for equilibrium in the vertical plane, the mass must be balanced exactly by the buoyancy force. The state of equilibrium in a given submergence depth tends to be unstable. A slight upward or downward movement from this position will result in the boat moving away from this initial position. Further, variation in buoyancy will occur continuously due to small changes in seawater density in the vertical and horizontal planes, while variation in weight will mainly be due to the consumption of stores, ballast, or collection samples. These will also have a significant influence on the ability to control the submersible in the vertical plane.

Most submersibles have an operational requirement to stop or move at very low speed (hover condition). It can be contrived to keep weight and buoyancy as nearly equal as possible, and means or special control devices for doing so are provided. Another reason for neutral buoyancy is related to safety. If the submersible is in power failure and not in neutral buoyancy, it will lose depth control. If lighter than buoyancy, it will rise uncontrolled to the surface. It must, however, be a safety design criterion for HOV. The opposite situation, i.e., heavier than buoyancy, is potential disaster when the submarine will plunge beyond its collapse depth or hit the sea bed.

Main Ballast Tanks (MBTs)

To keep the depth control, the main ballast tanks (MBTs) are fitted in a suitable location for the submersible where it is flooded or discharged with seawater, either wholly or partially. When it submerges, the submersible must either increase its weight or reduce its buoyancy. Conversely, an increase in buoyancy or a reduction in weight leads it to rise from submerged to surface.

Solid Droppable Ballast

For deep submersible, which is likely to be for exploration, some solid droppable ballast will be

added. The initial weight is larger than buoyancy, which leads the submersible to sink quickly. When the given depth arrives, part of the solid ballast will be abandoned. Then the submersible will be in the hover condition. After cruising is finished, the rest of the solid ballast will be thrown away. The weight is much less than the buoyancy, and the submersible will be back to the surface quickly.

Buoyancy Material

Adjustment of the relationship of weight and buoyancy is operated by flooding or discharging the seawater in MBTs. They can be readily enough flooded from the sea through the tanks valves, but discharging water from the tanks is not so easy. The water can be blown out to sea using high-pressure air, but that is noisy and subsequent venting of the tanks raises atmospheric pressure inside the boat. Alternatively, a pumping system can also be used to discharge to sea, and all the piping is required to withstand diving pressure. It may be useless for the deep submersible.

Some solid buoyancy material will be adopted for the deep submersible. The MBTs are fully flooded, and most of the buoyancy will be provided by this material when it is submerged in deep sea. The MBTs are only discharged when the submersible is almost back to surface, which help to float on the surface better.

Compensating Tanks

Compensating tanks are used for correcting the trim of a submerged AUV/ROV/HOV, which usually is composed of two tanks, one forward and another afterward. To correct the longitudinal balance, one tank will be emptied and another filled. The amount of correcting depends on the current situation of the submerged submersible.

AUV/ROV/HOV Propulsion System

Yunsai Chen and Kun Liu

Department of Technology, National Deep Sea Center of China, Qingdao, Shandong, China

Synonyms

Autonomous underwater vehicle (AUV); Brushless DC motor (BLDCM); Human-occupied vehicle (HOV); Magnetohydrodynamics (MHD); Remote operated vehicle (ROV); Tandem propulsion system (TPS)

Definition

The AUV/ROV/HOV propulsion system is an underwater energy conversion device that converts other forms of energy into kinetic energy of AUV/ROV/HOV. It consists of several thrusters that work together to propel the AUV/ROV/HOV to complete various complex movements underwater, such as cruise, search, hover, and other complex sports. Due to different missions, different underwater vehicles have different requirements for their own propulsion systems. In general, the propulsion system of an underwater vehicle should have good maneuverability, efficient propulsion efficiency, and low weight.

Scientific Fundamentals

Fundamentals of Propulsion System

Theory of Ideal Thruster

A disk surface of diameter D having no thickness has the function of absorbing external power and pushing water to obtain an axial induction speed so that the ideal disk surface is called ideal thruster, also called agitating plate. The ideal thruster makes the following simplifying assumption: an ideal and incompressible fluid; thruster operating in an

unbounded inflow; an actuator disk with no thickness and the water is accelerated only in the axial direction when passing through the disk; velocity and pressure distributions over the disk are uniform. As shown in Fig. 1, when passing through the ideal thruster, the velocity and pressure of the control volume will change.

Thrust and induction velocity of ideal thruster:

1. Fluid quality flowing through the agitating plate per unit time:

$$m = \rho A_0 (V_A + \mu_{a1})$$

A_0 – disk area, $A_0 = \pi D^2/4$

ρ – density of water

V_A – around the fluid velocity of disk

2. The momentum of inflow:

$$mV_A$$

The momentum of outflow:

$$m(V_A + \mu_a)$$

The momentum of increment:

$$m(V_A + \mu_a) - mV_A = m\mu_a = \rho A_0 (V_A + \mu_{a1}) \mu_a$$

3. According to the momentum theorem: the force acting on the fluid is equal to the increment of momentum per unit time (ideal thrust):

$$T_i = \rho A_0 (V_A + \mu_{a1}) \mu_a \quad (1)$$

4. Application of Bernoulli's equation

Far upstream to the front side of the disk:

$$P_0 + \frac{1}{2} \rho V_A^2 = P_1 + \frac{1}{2} \rho (V_A + \mu_{a1})^2 \quad (2)$$

The rear side of the disk to far downstream:

$$P'_1 + \frac{1}{2} \rho (V_A + \mu_{a1})^2 = P_0 + \frac{1}{2} \rho (V_A + \mu_a)^2 \quad (3)$$

Subtracting one equation from another:

AUV/ROV/HOV Propulsion System, Fig. 1 Pressure and velocity of ideal thruster

$$P_i = P'_1 - P_1$$

The disk thrust is equal to the pressure difference:

$$T_i = A_0(P'_1 - P_1) = \rho A_0 \left(V_A + \frac{1}{2} \mu_a \right) \mu_a \quad (4)$$

5. By comparing Eqs. (1) and (4), the induction velocity at the disk surface can be obtained:

$$\mu_{a1} = \frac{1}{2} \mu_a \quad (5)$$

μ_{a1} – axial induction velocity of the disk

μ_a – axial induction velocity of far downstream

Propeller Propulsion Theory

The movement of underwater vehicles is usually achieved by propellers, which are simple and widely used thrusters. The function of a propeller is to convert the torque to thrust. Thrust is another name for force, and a basic axiom of

mechanics tells us that force (thrust) is equal to mass multiplied by acceleration. In other words, if we apply acceleration to a large amount of water, we will generate thrust or push that will accelerate the underwater vehicle forward when a large amount of water moves in the opposite direction. As shown in Fig. 2, the blades of the propeller and the shaft are supported on the propeller hub at a certain angle, and the propeller hub is driven by the propeller shaft. When the propeller rotates one revolution, the forward distance in the axial direction is called the process, and the difference between the pitch and the process is called slippage, and the ratio of slippage to pitch becomes the slip ratio, which can be expressed as:

$$S_a = \frac{H - v/n}{H} \quad (6)$$

S_a – slip ratio

H – slip, m

n – propeller rotate speed, rpm

v – the speed of underwater vehicles, m/S_o

AUV/ROV/HOV Propulsion System, Fig. 2 Propeller

In order to generate thrust, the propeller must accelerate or move a large amount of water astern. Now, when the propeller rotates, it looks like a screw and slides over the water without moving any water. If this happened, the propeller would advance an amount equal to the propeller pitch, which is called zero slip. But in order to produce thrust, we must accelerate or move water, and therefore, it is apparent that the propeller will not advance the full amount of pitch in each revolution. In order to generate thrust, we must have slip, and the amount of slip will be proportional to the thrust required by the vehicle. The propeller thrust T can be expressed as:

$$T = \rho n^2 D^4 K_T \quad (7)$$

ρ – the density of water, kg/m^3
 n – propeller rotation speed, rps
 D – propeller diameter, m
 K_T – thrust coefficient

In order to generate this thrust, a torque must be applied to the propeller to rotate the propeller and the water is pushed out by the blades. The torque Q can be expressed as:

$$Q = \rho n^2 D^4 K_Q \quad (8)$$

K_Q – torque coefficient

Thrust coefficient and torque coefficient are both functions of propeller geometric parameters.

Thruster Type

The core component of the propulsion system is the thruster. Different types of thrusters have been

AUV/ROV/HOV Propulsion System, Fig. 3 Electric thruster

developed according to the type of underwater vehicle and the environment in which it is used. At present, the thrusters commonly used in AUV/ROV/HOV propulsion systems mainly include electric thrusters, hydraulic thrusters, water-jet thrusters, hubless rim-driven thrusters, tandem thruster system, magnetohydrodynamic drive thruster, bionic thrusters, etc.

Electric Thruster

Most battery-powered underwater vehicles use motors to directly drive the propeller. DC motors and AC motors can be used. The DC motor has low cost, the speed control and the control system are simple, and the AC motor needs the inverter to convert the DC into AC, which has high cost and complicated system. In particular, underwater vehicles that use battery packs as a power source use DC motors. Brushless DC motor is a new type of DC motor developed with the rapid development of electronic technology in recent years. Its most prominent feature is that there is no complicated commutation mechanism. Usually, permanent magnet is used as rotor and has no excitation loss, no commutation spark, no radio interference, easy operation, and maintenance (Fig. 3).

Hydraulic Thruster

Some large and medium-sized underwater vehicles use hydraulic motors as propulsion power. Compared with the underwater motor, the thruster with hydraulic motor has the following advantages: the hydraulic propulsion system controlled

AUV/ROV/HOV Propulsion System, Fig. 4 Hydraulic thruster of sub-Atlantic

AUV/ROV/HOV Propulsion System, Fig. 5 Hubless rim-driven thruster

by the flow has good speed regulation performance, and it is easy to realize stepless speed regulation in a wide range; the hydraulic propulsion system usually has hydraulic compensation, and it is easier to realize the sealing of the system; the safety is good, the reliability is high, the installation position is flexible, and the cost is low. As shown in Fig. 4, the hydraulic thrusters manufactured by Sub-Atlantic are used in many ROVs.

Water-Jet Thruster

The water-jet thruster is a propulsion device that uses the reaction of the high-speed water jet ejected from the jet pipe to provide thrust. It is similar to the aviation jet thruster, except that water instead of air combustion mixed gas is used as the working medium. After the water is obtained at a high speed by a large-flow high-pressure water pump installed on the underwater vehicle, the jet is ejected to generate thrust. The advantage of the water-jet propulsion device is that almost all accessories on the underwater vehicle are eliminated; the loss of the shafting and transmission and the loss of the thruster's cavitation are eliminated; the underwater vehicle can be easily manipulated.

Hubless Rim-Driven Thruster

In recent years, a propulsion device integrating the structure of a powerful motor and a propeller has appeared, which is called hubless rim-driven

thruster (Yan et al. 2017). As shown in Fig. 5, the hubless rim-driven thruster is mainly composed of ducts, propeller blades, armature, rare-earth magnetic steel, front and rear sliding bearings, bearing supports, and other components. The hubless rim-driven thruster integrates the rotor of the motor with the propeller blades of the thruster. The stator of the motor is integrated into the duct of the thruster. When the motor is running, the rotor of the motor drives the propeller blades to rotate, generating thrust and driving the vehicle to sail. The propeller blades without hub are supported by two sliding bearings that are fixed to the front and rear ducts. Without the rear guide vanes, the space occupied by the propeller hub can be fully utilized, and the blades can be protected from external impurities damage. Due to its compact structure, high efficiency, low vibration and noise, good cooling conditions, no need for dynamic sealing, modular design and disassembly, it has become a hot research topic in the field of underwater vehicles (Song et al. 2015).

Tandem Propulsion System (TPS)

In 1961, American engineer F. R. Haselton proposed the concept of tandem propulsion system (TPS) (Nanba and Shimizu 1988). After more than 20 years of efforts, in 1985, the engineers of Ametek designed and manufactured an underwater vehicle with TPS. The TPS requires two propellers that are oriented in the longitudinal

AUV/ROV/HOV Propulsion System, Fig. 6 Tandem thruster system

direction of the underwater vehicle (usually mounted on the bow and stern respectively), allowing for flexible control of the underwater vehicle in 6 degrees of freedom, as shown in Fig. 6. This type of propulsion system actually places the stator of the electric machine in the underwater vehicle and supports the rotor on the outer casing of the underwater vehicle, and the blade is directly mounted on the rotor. It differs from a conventional underwater vehicle propeller in that the pitch of the blade of a conventional propeller is usually unchanged, while the blade of the omnidirectional propeller changes at every moment, and the pitch variation of each blade is not according to the same law.

Compared with other thrusters, TPS is simple in construction, easy to manufacture, and maintain, especially, when the diameter of the vehicle is limited, TPS has higher efficiency than conventional thrusters, thus saving energy and reducing ROV cable diameter and cable resistance. For HOV and AUV, the weight and volume of the power supply can be reduced. TPS can better absorb external load changes and reduce the impact on underwater vehicles, and because its power and thrust are borne by two sets of blades, TPS has better tail vibration performance than conventional thrusters. In addition, the tail shaft of the TPS system is long, the weight is large, the price is high, the seal is easy to leak, and the control system is complicated and requires computer-aided control. Therefore, the TPS system has not been put into practical use yet, but it represents one of the developments of the underwater vehicle propulsion system, and it will be widely used in future.

Magnetohydrodynamic Drive Thruster

A magnetohydrodynamic drive thruster or MHD accelerator is a method for propelling underwater vehicles using only electric and magnetic fields with no moving parts, accelerating an electrically conductive propellant (liquid or gas) with magnetohydrodynamics (Takeda et al. 2005). The fluid is directed to the rear and as a reaction, the underwater vehicle accelerates forward.

The working principle involves the acceleration of an electrically conductive fluid by the Lorentz force, resulting from the cross product of an electric current (motion of charge carriers accelerated by an electric field applied between two electrodes) with a perpendicular magnetic field. The Lorentz force accelerates all charged particles (positive and negative species) in the same direction whatever their sign, and the whole fluid is dragged through collisions. As a reaction, the vehicle is put in motion in the opposite direction. This is the same working principle as an electric motor (more exactly a linear motor) except that in an MHD drive thruster, the solid moving rotor is replaced by the fluid acting directly as the propellant (Bui et al. 2010).

MHD thrusters are classified into two categories according to the way the electromagnetic fields operate: Conduction devices and induction devices. Conduction devices when direct current flows in the fluid due to an applied voltage between pairs of electrodes, the magnetic field being steady. Inductive devices when the alternating current is caused by a rapidly changing magnetic field, such as eddy currents. In this case, no electrode is required.

MHD is attractive for underwater vehicle applications because it has no moving parts, which means that a good design might be silent, stealthy, reliable, and efficient. Additionally, the MHD design eliminates many of the wear and friction pieces of the drivetrain with a directly driven propeller by an engine. The major problem with MHD is that with current technologies, it is more expensive, and much slower than a propeller driven by an engine. In 1991, the world's first full-size prototype Yamato 1 was completed in Japan after 6 years of R&D by the Ship & Ocean Foundation (Fig. 7). The ship successfully carried a

AUV/ROV/HOV Propulsion System, Fig. 7 MHD Thruster of Yamato I

AUV/ROV/HOV Propulsion System, Fig. 8 RoboTuna II

crew of 10 plus passengers at speeds of up to 15 km/h in Kobe Harbor in June 1992.

Bionic Thruster

The traditional underwater propulsion system is propeller propulsion, but the efficiency is relatively low. Modern bionic technology provides new ideas for the development of new water propulsion systems. Fish and other marine life have evolved in the ocean for millions of years, and their perfection is beyond imagination. The data shows that fish in the ocean by the fins and body twist to provide forward momentum, jellyfish through the squeeze and shrink umbrella to provide forward momentum, its advancement is almost perfect, and the efficiency is as high as 98% (Naomi 2000).

At present, many countries are actively developing bionic underwater vehicles, such as Charlie I and RoboTuna II of Massachusetts Institute of Technology, as shown in Fig. 8, UPF-2001 and PF-700 of Japan's National Marine Research Center, Bionic Robotic Eel, and SPC of Beijing University of Aeronautics and Astronautics.

Because the performance of materials is far from the advanced level of marine biological muscles, the biomimetic vehicle test platform or prototype developed by scientists in various countries at present is a simple mechanical transmission to simulate the promotion of marine organism.

However, the test results of various countries show that the propulsion efficiency of these bionic thrusters is higher than that of ordinary propeller propulsion. Therefore, with the deepening of research and breakthroughs in key technologies, the bionic thruster will be more widely used.

Control Allocation of Thrust

Control allocation of thrust is the core of the control system of underwater vehicles (Liu et al. 2018). By properly arranging the number and position of the thrusters on the surface and inside of the vehicle, and properly setting the thrust of each thruster, the complex underwater movement of the submersible is completed (Sordalen 1997), as shown in Fig. 9. The underwater vehicle is a highly nonlinear coupled system with high nonlinearity. It is difficult to obtain accurate hydrodynamic coefficients, so it is difficult to establish accurate maneuvering motion models (Johansen et al. 2004). At the same time, environmental disturbances, such as ocean currents, are difficult to predict (Lindegard and Fossen 2003). Therefore, most propulsion system power distribution does not depend on precise mathematical models. Intelligent control combines the artificial intelligence method with the feedback control theory and has obvious advantages in dealing with

AUV/ROV/HOV Propulsion System,

Fig. 9 Thrusters distribution of “Jiaolong” HOV

complexity and uncertainty. Therefore, when the system thrust distribution is promoted, the intelligent control method can obtain sound control effects. At present, the intelligent control methods commonly used in underwater vehicle propulsion systems mainly include classical PID control, fuzzy control, neural network control, synovial variable structure control, and S-plane control method (Cao et al. 2013).

Motor of Thruster

The brushless DC motor (BLDCM) has the advantages of simple structure, high efficiency, reliable operation, low mechanical noise, good speed regulation, etc., and is widely used in underwater thrusters. Conventional brushless DC motors cannot be used directly in seawater high-pressure environments, and motors for underwater thrusters require unique design. First, in order to prevent the brushless DC motor from being damaged by high pressure, the motor housing must be filled with insulated aviation hydraulic oil and connected to a compensator installed inside or outside the thruster to ensure that the oil pressure in the motor housing is always slightly higher than the external seawater, to prevent external seawater from entering the motor housing. Secondly, the waterproof and pressure-resistant design of the motor drive circuit, the housing of motor drive circuit is mainly divided into waterproof electronics housing and wet electronics housing. The waterproof electronics housing is protected against seawater pressure by adding a pressure-proof sealed casing to isolate

AUV/ROV/HOV Propulsion System, Fig. 10 Waterproof electronics housing

seawater and ensure the drive circuit is at operating pressure. Working in the environment, the drive circuit does not need special design, as shown in Fig. 10. In the wet electronics housing, the drive circuit is directly immersed in the oil to isolate the seawater by oil, but the drive circuit components need to withstand the pressure of the surrounding oil, so components that cannot

withstand pressure need to be designed with special protection packages.

Rotary Dynamic Seal of Underwater Thruster

When rotating, there is a gap between the shaft and the motor housing. In order to transfer the torque of the motor to the propeller, the problem of the rotary dynamic seal of the shaft must be solved. If an O-ring is added between the shaft and the motor housing, the O-ring will wear, heat, and deform when the shaft rotates at high speeds, and is liable to leak under high seawater pressure. Current practice has proved that the method of adding O-ring seal is not reliable. For this reason, engineers and technicians have developed a variety of advanced dynamic sealing devices, including mechanical dynamic seals, underwater rotary oil seals, and magnetic coupling isolation seals and so on.

Mechanical Dynamic Seal

The essence of the mechanical dynamic seal is to convert the clearance between the shaft and the housing into the clearance between the static ring and the moving ring. The static ring is connected with the motor housing and remains stationary. The moving ring is connected with the motor shaft and rotates following with the motor shaft. Therefore, only the contact surface of the moving ring and the static ring has clearance, as shown in Fig. 11. However, the static ring is made of tungsten carbide, known as hard ring, the moving ring is made of impregnated resin graphite, known as

soft ring, and the two mutual contact surfaces are processed into a mirror, moving ring, and static ring tightly contact together by spring pressure. The moving ring, bushing, spring seat, and the tightening hoop are fixed into one. When the tightening hoop and the motor shaft are tightened, the moving ring can rotate with the motor in the same axis. Because the moving ring is soft ring easy to wear, when following the motor shaft rotation, there will form oil film between the moving ring and the soft ring, and the oil film fills the gap between the contact surface of the moving ring and the stationary ring, so as to prevent seawater from flowing through the contact surface. The thrusters of the 300 m underwater vehicle RECON-IV of Shenyang Institute of Automation used mechanical dynamic seal and achieved good application effect. At present, because of the complex structure, such structures cannot guarantee zero leakage, mechanical dynamic seal has been rarely used in underwater environments.

Underwater Rotating Oil Seal

The underwater rotating oil seal can be used for the sealing of pressure compensated thrusters (Li 2005). The oil-filled pressure compensator always maintains motor housing pressure higher than the external seawater pressure of 0.2–0.7 bar, so the inside pressure of the oil seal is slightly higher than the outer side, thus achieving a good sealing effect, as shown in Fig. 12. This sealing method is simple and reliable but does not guarantee zero leakage. The 4500-m “Deep-Sea Warrior” HOV

AUV/ROV/HOV Propulsion System,
Fig. 11 Structure of mechanical dynamic seal

AUV/ROV/HOV Propulsion System, Fig. 12 Oil seal of underwater thruster

AUV/ROV/HOV Propulsion System, Fig. 13 Cylindrical magnetic coupling isolation seal

developed in China uses this sealing method and has completed more than 100 diving missions with good performance (Liu et al. 2016).

Magnetic Coupling Isolation Seal

The magnetic coupling isolation seal of underwater thruster converts the mechanical energy of the motor into magnetic energy, which is then converted into the mechanical energy of the propeller. According to the structural characteristics, it can be divided into cylindrical structure and planar structure. As shown in Fig. 13, the cylindrical magnetic coupling isolation seal is mainly composed of inner ring, outer ring, and isolating sleeve. The inner and outer rings are filled with high-remnance permanent magnets by U-shaped groove soft iron. The isolation sleeve is made of stainless steel or titanium alloy, and the magnetic permeability is good. The “Jiaolong” HOV thrusters use this sealing method. As shown in Fig. 14, the planar magnetic coupling isolation seal mainly consists of the original moving surface, isolation sleeve, and follow-up surface. Both the original moving surface and follow-up surface are inlaid with high remanence permanent magnets. Under the suction of the magnet, the follow-up surface rotates following the original moving surface and transmits torque. This seal has a large

AUV/ROV/HOV Propulsion System, Fig. 14 Surface magnetic coupling dynamic seal

axial force and is therefore only suitable for low-power thrusters.

Key Applications

Propulsion System of “Qian Long-III” AUV

As one of the representatives of the AUV, the propulsion system of “Qian Long-III” consist of five thrusters, including four Kort-nozzle main thrusters and one horizontal channel thruster, as shown in Fig. 15. These thrusters are designed as oil-filled compensation. The special pressure-resistant package design of the circuit components ensures that the drive circuit can work in a high-pressure environment, while the oil seal ensures that the motor extends out of the shaft and is reliably sealed. Under the control allocation system of thrust, “Qian Long-III” can get the maximum speed of 2.5 kN, and sail more than 30 h at the speed of 2.0 kN. In April 2018, in the South China Sea, the “Qian Long-III” sailed 156.82 km

and 42.8 h in a single dive and created a new record for China’s deep-sea AUV (Li et al. 2018).

Propulsion System of “Hai Long-III” ROV

As one of the representative of ROV, the propulsion system of the “Hai Long-III” HOV is composed of seven thrusters, including four horizontal thrusters and three vertical ones, as shown in Fig. 16. These thrusters are driven by hydraulic motors, and the hydraulic source of the hydraulic motors is provided by a main hydraulic pump station via a seven-way servo hydraulic control valve box. The hydraulic pump station can provide a flow rate of 232 l pm and pressure of 285 bar, the servo hydraulic control valve can adjust the flow rate of pipelines and then adjust the speed of the thrusters. Under the control allocation system of the seven-way servo hydraulic valve, the “Hai Long-III” can get maximum forward and backward speed of 3.2 kN, maximum lateral moving speed of 2.4 kN, and maximum vertical moving speed of 2.0 kN. At present, “Hai Long-III” has carried out several sea tests, and its hydraulic propulsion system works well.

AUV/ROV/HOV Propulsion System, Fig. 15 The “Qian Long-III”

Propulsion System of “Jiaolong” HOV

As one of the representatives of HOV, the propulsion system of “Jiaolong” HOV is composed of seven thrusters, including four Kort-nozzle main thrusters in the tail, one horizontal channel thruster at the bow, and two rotary Kort-nozzle thrusters at the middle, as shown in Fig. 17. These thrusters use dry housing and wet housing isolation design, integrated built-in oil-filled compensator, magnetic coupling isolation seal drive, etc., to ensure reliable functioning for long time in the

AUV/ROV/HOV Propulsion System, Fig. 16 Structure of “Hai Long-III”

AUV/ROV/HOV Propulsion System, Fig. 17 “Jiaolong” HOV

high-pressure seawater environment (Cui 2013). Under the control allocation system of thrust, the “Jiaolong” HOV can get maximum forward speed of 2.5 kN, cruise speed of 1.0 kN, maximum transverse velocity of 0.7 kN, and maximum dynamic vertical transfer velocity of 0.7 kN. So far, “Jiaolong” HOV has made more than 150 dives, and its propulsion system is working well.

AUV/ROV/HOV Resistance

Zhe Jiang and Pengfei Sun

Shanghai Engineering Research Center of Hadal Science and Technology, Shanghai Ocean University, Shanghai, China

Synonyms

[Appendage resistance](#); [Form resistance](#); [Frictional resistance](#); [Hull resistance](#); [Resistance](#); [Viscous resistance](#)

Definition

When the underwater vehicles such as AUVs/ROVs/HOVs or submersibles navigate in the

sea, they will inevitably suffer the resistance of the water as they move in the water fluid medium. Therefore, the reaction force of the water on the hull is called the resistance. The resistance of the submersible is usually divided into the resistance of the bare hull and the resistance of appendage (Renilson 2015). Appendage resistance refers to the increase in the resistance value of the appendage structure, such as rudders, stabilizers, manipulators, thrusters, etc., which overhung on the naked hull. From the mechanical point of view, the resistance of the submersible consists of the frictional resistance because of the tangential force along the surface of the hull and the pressure resistance because of normal force which is exerted on the surface of the hull. Unlike the ship hull, since the submersible does not have a free surface, the pressure resistance exists only in the composition of the viscous pressure resistance, and there is no wave-making resistance.

Scientific Fundamentals

Method for Studying the Submersible Resistance

Methods for studying the resistance of submersibles include theoretical analysis, experimental research, and numerical calculation (Sheng 2003). Theoretical analysis can only be applied to simple problems and qualitative analysis because of the simplification of the object. Experimental method has the characteristics of strong authenticity and high reliability relative to theoretical research; but due to the cost, project duration, and other constraints, experimental method is generally only used to validate the results of numerical methods. The towing tank test and wind tunnel test are the mostly used experimental methods currently. In recent years, with the rapid development of computer technology, computational fluid of dynamics (CFD) method in the hydrodynamic performance of submersibles are applied in more and more applications. Compared to traditional theoretical and experimental methods, CFD methods have the advantages of short time consumption and low cost.

Classification of Submersible Resistance

There are many appendage structures on the surface of the submersible, including the rudder, manipulator, thruster, underwater camera, underwater lighting, sampling basket, etc., so the submersible resistance can usually be divided into the resistance of the bare hull and the resistance of appendage according to the structure of the submersible.

From mechanical point of view, the main source of resistance of the submersible under water is the tangential force along the surface of the hull and the normal force which is perpendicular to the surface of the submersible, which are the frictional resistance and the viscous pressure resistance respectively.

According to the boundary layer theory, a boundary layer is formed on the surface when the viscous water flows through the submersible, and the rate of change of the fluid velocity in the boundary layer is prominent. According to the Newton internal friction law, the frictional shear stress on the surface of the submersible is great, so the resultant force of these frictional shear forces is the frictional resistance of the submersible. In scientific research, the frictional resistance can be thought of as the sum of the smooth plate frictional resistance with the same wetted surface, the same length and speed, and the additional frictional resistance after considering the tortuosity and roughness. In the theoretical study, scholars often use the formula to estimate the frictional resistance. After comparing with the experimental data, it can be proved that these formulas have appropriate precision within limits.

The viscous pressure resistance is another component of the resistance of the submersible, in essence, due to the viscosity of the fluid. It is known from the theory of fluid mechanics that a lot of vortices appear in the rear part of the hull when boundary-layer separation occurs, causing a difference in fore and aft pressure, which causes resistance. This resistance is called viscosity pressure resistance. Sometimes, it is also referred as vortex resistance. There are various methods for measuring the viscosity pressure resistance, and the most commonly used method is the wake pressure measurement method. In the actual

research, in order to avoid the tediousness of the experiments and to obtain the value of the viscosity pressure resistance, the Froude two-dimension method and the three-dimensional method which is proposed in the 1950s can be used.

Factors Affecting the Resistance of the Submersible

The hull form is the most important factor which is affecting the resistance performance of the submersible. The following two parameters are the most sensitive parts of the resistance performance of the submersible (Renilson 2015).

1. L/D : Aspect ratio. Where L is the submarine length, D is the diameter.
2. $C_p = \frac{\nabla}{A_M L}$: Prismatic coefficient. Where ∇ is the volume of the submarine and A_M is midships cross-sectional area.

In addition, the fore body form, the parallel middle body length and shape, and the aft body form all affect the resistance performance of the submersible.

Key Applications

Studying the resistance performance of the submersible is of great significance for improving the cruising speed for AUV/ROV/HOV.

Methods on Measuring Submersible Resistance

There are generally three methods to measure the drag of submersible: empirical equation estimation, model test method, and computational fluid dynamics (CFD) method. In different design phases of submersible, different methods are used.

Empirical Equation Estimation (Cui et al. 2018)

For submersibles moving underwater, if the depth exceeds one coxswain, the total resistance can be expressed as:

$$R_t = R_f + R_{pv} + R_{ap}$$

$$= \frac{1}{2} \rho V^2 (C_f + \Delta C_f + C_{pv} + C_{ap}) \quad (1)$$

In the formula, " R_t " is the total resistance.

" R_f " is the frictional resistance.

" R_{pv} " is the viscous pressure resistance.

" R_{ap} " is the appendage resistance.

" ρ " is the fluid density.

" V " is the submersible speed.

" C_f " is the frictional resistance coefficient.

" ΔC_f " is the roughness coefficient.

" C_{pv} " is the viscous pressure resistance coefficient.

" C_{ap} " is appendage resistance coefficient.

- (1) Empirical formula for calculating frictional resistance

The following three formulas can be used to calculate the friction resistance of submersible.

1. Schoenherr formula

$$\frac{0.242}{\sqrt{C_f}} = \lg(R_e C_f) \quad (2)$$

When $R_e > 10^6 - 10^9$, the formula is equal to:

$$C_f = \frac{0.4631}{(\lg R_e)^{2.6}} \quad (3)$$

2. ITTC formula

$$C_f = \frac{0.075}{(\lg R_e - 2)^2} \quad (4)$$

3. Prandtl-Schlichting formula

$$C_f = \frac{0.455}{(\lg R_e)^{2.58}} \quad (5)$$

- (2) Empirical formula for calculating viscous pressure resistance

$$C_{pv} = C_\phi \cdot K \cdot \frac{A}{S} \quad (6)$$

In the formula, $K = f(B/H)$.

" S " is the wetted surface area.

" C_ϕ " can be expressed as follow:

$$C_\phi = f\left(L_A / A^{\frac{1}{2}}, \phi\right) \quad (7)$$

“ L_A ” is the length of outlet section;

“ ϕ ” is the longitudinal prismatic coefficient, $\phi = \nabla/L \cdot A$.

“ A ” is the midship section area.

- (3) Empirical formula for calculating appendage resistance

The appendage resistance can be expressed as follows:

$$C_{ap} = \sum C_{scf} \cdot \frac{S_{SC}}{S} + K_{SC} \cdot C_{pv} \quad (8)$$

In the formula, “ C_{scf} ” is frictional resistance coefficient on control surface.

“ S_{SC} ” is the wetted surface area on control surfaces.

“ K_{SC} ” is the empirical coefficient.

“ C_{pv} ” is viscous pressure resistance coefficient on naked bodies.

The Towing Tank Test

The towing tank test is one of the most used experimental methods to obtain the resistance of underwater vehicles, ships, etc. Due to the limitation of facilities of any towing tanks, scaled-sized models are generally used instead of real size models. In the towing test, the scaled model is usually mounted on the trailer through the support rod, and the resistance of the model is measured in all directions through the movement of the trailer, which simulates the movement of

the submersible. The real body resistance can be converted by the model resistance through the similarity laws. Froude similarity theory is often used for resistance conversion in engineering experiments. A towing tank test of a full ocean depth submersible is shown in Fig. 1 (Jiang 2016).

Resistance Analysis Using Computational Fluid Dynamics (CFD) Method

Empirical equation estimation has poor adaptability varying with different shapes and characteristics of different types of submersibles. Towing tank model test is costly and time consuming. Compared to experimental method, using CFD analysis in the resistance analysis will be much faster and require relatively low cost. In addition, in principle it is possible to use CFD to obtain results at full-scale Reynolds numbers, something which is not possible using model experiments. On the other hand, the analysis object can be modeled according to the shape or molded lines of it, and even appendages or local contour can be simulated in a CFD analysis; the results obtained through CFD analysis will be more accurate and reliable compared to using empirical equation estimation. Therefore, the CFD method is usually adopted to conduct flow field simulation, especially in the early stage of submersibles' design, and numerical calculation model is built in CFD software to obtain submersibles' resistance.

AUV/ROV/HOV Stability

Jinfei Zhang
Shanghai Engineering Research Center of Hadal Science and Technology, Shanghai Ocean University, Shanghai, China

Synonyms

[Intact stability](#); [Longitudinal stability](#); [Metacentric height](#); [Restoring moment](#); [Stability at large angles](#); [Stable equilibrium](#); [Transverse stability](#)

Definition

Stability is a kind of ability to enable an AUV/ROV/HOV to restore the original position after deviating from the equilibrium position under disturbing force. The distance, BG, between the center of gravity (G) and the center of buoyancy (B), governs the stability characteristics of the submerged submersible. For a surfaced boat, the measure of the stability is given by the distance GM (metacentric height). Thus, to be in stable equilibrium when the *surfaced boat* upright, the vertical position of the

center of gravity (G) should be sufficiently below that of the center of buoyancy (B) or metacenter (M).

Scientific Fundamentals

For the submerged AUV/ROV/HOV, only intact stability needs to be considered because there is no reserve of buoyancy. Hydrostatic stability, both transverse and longitudinal, i.e., in heel and pitch, is described by the position relationship between the center of gravity (G) and the center of buoyancy (B). The distance, BG, governs the stability characteristics of the submersible, which determines the restoring moment when it experiences an angle of heel or an angle of pitch.

The criteria for the magnitude of BG are in relation to several circumstances: (Burcher and Rydill 1994).

- (a) Static: It has sufficient BG that moving weights or men on board athwartships or fore and aft does not cause a large change of attitude.
- (b) Dynamic: The value of BG affects the behavior of the submersible when proceeding at speed submerged. If it changes course at speed, there is a tendency to cause a heeling moment and to result in a very large heel angle. During a turn, BG provides a hydrostatic moment to the hull resisting heeling and pitching motion. At very slow speeds, the hydrostatic moment results in the depth control surfaces no longer cause the boat to dive, but instead cause it to angle down by the bow while experiencing an upward rising motion.
- (c) Transition: The transverse metacenter moves from the center of buoyancy to the position of metacenter appropriate to the surface waterline in the transition from the submerged to the surfaced condition. The center of gravity also moves owing to the removal of water from the MBTs, which gives a free surface effect. It is necessary to ensure that during transition the migrating center of gravity is not above the metacenter.

Transverse Stability

For a submerged AUV/ROV/HOV to be stable in roll, known as transverse stability, the center of buoyancy (B) must be above the center of gravity (G), termed as positive BG value, as shown in Fig. 1a. In this case, if the boat is heeled to a small angle, as shown in Fig. 1b, the hydrostatic moment on it will cause it to return to the upright. On the other hand, if G is above B, at a small angle heeling under an external moment, the hydrostatic moment will cause it to continue to heel, as shown in Fig. 1c. (Martin Renilson 2015).

When the submersible is floating on the surface, the situation is different. In this case, the center of buoyancy (B) moves transversely as a function of heel angle. For small angles, the upward force, through the center of buoyancy (B), always acts through the metacenter, designated as “M” in (d). Thus, for a surfaced boat to be in stable equilibrium when upright, the position of metacenter (M) has to be above the center of gravity (G), and measure of the stability is given by the distance GM (metacentric height).

The formula of the vertical distance between the center of buoyancy (B) and the metacenter (M) is given as follows: $BM = I / \nabla$, where I is the second moment of area of the waterplane around the longitudinal axis and ∇ is the immersed volume. When the submarine is submerged, I will be equal to zero, and hence the position of metacenter (M) will be the same as the position of the buoyancy center (B).

Longitudinal Stability

Similar as transverse stability, the same principles apply to a submerged AUV/ROV/HOV as to a floating surface ship. However, the lack of a waterplane results in a very small restoring moment in the longitudinal direction if the submersible is in the pitch motion. Thus, it is essential to have the longitudinal position of the center of gravity (G) lined up with the longitudinal position of the center of buoyancy (B). As the longitudinal position of the center of gravity moves during a voyage due to use of consumables, sample collection, etc., it is necessary to be able to adjust this by use of ballast tanks or other suitable methods.

Stability at Large Angles

As well as designing an AUV/ROV/HOV to have positive surface flotation at a reasonably level trim, there is also the need to satisfy the heel stability criterion by having a positive GM (metacentric height). A submersible on the surface has very small reserves of buoyancy compared with surface ships. On the other hand, with its small profile, the surfaced submersible does not face as much in the way of rolling excitation from wind and waves as most surface ships. The configuration of a submersible makes it difficult to provide the boat with large heel stability. Motion on the surface is usually characterized by slow large angle rolling, sometimes to alarming angles, whereas, fully submerged, little motion occurs.

AUV/ROV/HOV Stability, Fig. 1 When the submersible is floating on the surface, the situation is different. In this case, the center of buoyancy (B) moves transversely as a function of heel angle. For small angles, the upward force, through the center of buoyancy (B), always acts through

the metacenter, designated as “M” in (d). Thus, for a surfaced boat to be in stable equilibrium when upright, the position of metacenter (M) has to be above the center of gravity (G), and measure of the stability is given by the distance GM (metacentric height)

Hence, the surface is not the place for a submarine in heavy weather.

Renilson M (2015) Submarine hydrodynamics. Spring Briefs in Applied Sciences and Technology, United Kingdom

Key Applications

The stability characteristics of an AUV/ROV/HOV are governed by the distance of BG and GM for the submerged and surfaced condition, respectively. Therefore, enough attention must be paid to keep the vertical position of the center of gravity (G) sufficiently below that of the center of buoyancy (B) or metacenter (M), which leads to an adequate separation for the purposes of transverse and longitudinal hydrostatic stability.

Main Ballast Tanks (MBTs)

The purpose of the MBTs is to allow major adjustment of the submersible mass to enable it to operate submerged as well as on the water surface. Water and air enter and leave the MBTs through flooding holes at the bottom and vents at the top of the tanks. The size of the vents and the flooding holes will have a direct effect on how long it will take for the MBTs to fill, and small flooding holes may cause problems with overpressure and stability issues on the surface.

To improve the initial stability, the waterline areas should be as large as possible. The MBTs may be located at sides in transverse and at bow and stern in longitudinal, which gains the higher metacenter characteristic on the surface.

Compensating Tanks

Compensating tanks is usually composed of two tanks, one forward and another afterward. When the submersible submerged, adjustment ability of MSTs is lost, because it is fully flooded; compensating tanks can be used to correct the longitudinal balance by flooding or discharging of these two tanks separately, which hence effect on the stability of submersible.

Definition

Auxiliary icebreaking methods collectively refer to the application of auxiliary systems and/or technologies on the icebreaker to improve its icebreaking ability. They are usually used for the high-level icebreaker which works in high ice conditions. In contrast, conventional icebreaking method usually refers to that an icebreaker breaks ice by its own momentum and/or gravity, in either continuous or crash icebreaking ways (Ettema et al. 1987).

Scientific Fundamentals

As mentioned above, there are usually two traditional ways to break ice for an icebreaker: continuous or crash icebreaking ways. The former is to crush the ice by icebreaker's gravity, and the latter is to crash the ice by icebreaker's power mainly. As the thickness of ice increases, both methods become difficult, and the capacity of icebreaker will be limited. Under extreme conditions, when the ice thickness exceeds the icebreaking capacity of the icebreaker, the ship is possible to be blocked or trapped and even broken. At this time, auxiliary

icebreaking methods to improve the icebreaking capacity of the icebreaker become important, which will help the icebreaker get rid of trapped. Beyond that, fast and effective auxiliary icebreaking methods are also proposed to improve the performance of the ice breaker in normal working conditions. One can see various auxiliary icebreaking methods booming. To make it simple, we broadly classify auxiliary icebreaking methods into the following categories according to the working principles:

- Mechanical methods, which crush ice by accessory mechanical devices, such as mechanical ice cutting, Alex bow barge, mechanical saws, Archimedes screw vehicle, stem knives, bow ramp, mechanical impact devices, etc.
- Auxiliary ship movement methods, such as high-speed heeling system and pitching systems
- Auxiliary medium methods, which help to reduce ice resistance by adding auxiliary medium on the ship, such as water hull lubrication systems, bubbler systems, water jets, and low friction hull coatings
- Additional floating-body methods, which help to break ice by introducing additional floating bodies whose icebreaking principles can be various, such as explosive icebreaking barge, air cushion vehicles, upper Mississippi icebreaker, etc.

Mechanical Methods

Just as its name implies, mechanical methods enhances the icebreaking capability of the icebreaker by installing additional mechanical devices. These accessory mechanical devices could help to break ice directly, but they need to be installed on the ship rather than work independently. As shown in Fig. 1, these devices can be various. Based on the installation positions, they can be further classified into three types roughly. One is devices installed around the bow, including saws, planning tools, plow-form devices, etc. as shown in Fig. 1a and b. This kind

is most common, as bow is the principal part during icebreaking. The second one is devices suspended from the hull to the ice surface by suspenders, such as pneumatic actuators and pile hammers, as shown in Fig. 1c. Others are placed in the middle of the hull, such as two large counterrotating screws, as shown in Fig. 1d.

Under suitable conditions, mechanical devices can improve the efficiency of icebreaking and increase the safety of navigation in ice-covered areas. However, most of them are limited to research fields rather than actual engineering applications, because they change the shapes of the hull severely and induce a lot of problems when the ship moves in open water. Here we choose mechanical saws as the example to introduce its working principle and development process.

The mechanical saw is usually installed on the bow and has corresponding control devices to adjust its installation angle. Cut by the mechanical saw, the ice can be weakened in advance and even broken directly. The weakened ice or crushed ice will be further broken and pushed away by the hull. As a result, the channel is opened up. Various toothed blades, which can cut through the ice layer, can be adopted, such as direct saw, slitting saw, cross cut saw, chain saw, electric bow saw, etc. Stephens designed a semisubmersible oil tanker icebreaker with three steel ice saws mounted on its narrow superstructure, which could undercut the ice (Stephens 1973). In addition, some mechanical saws are equipped with thermal installations. The hot water discharged along the saw tooth reduces the blockage of the ice during icebreaking effectively. The Russians have extensively studied mechanical saws and report that model tests show devices using saws on channel clearing devices requiring 17–28% of the force to move a model of a typical icebreaker. However, there is no literature on full-scale devices in operation (Smith et al. 1981). Americans have also conducted extensive researches on mechanical saws and analyzed the application of such devices to meet the requirements for Coast Guard support in various domestic waterways (Lecourt and Voelker 1974). However, just mentioned above, this technology

(d) Archimedes screw

Auxiliary Icebreaking Methods, Fig. 1 Sketches of some typical mechanical auxiliary icebreaking methods (Smith et al. 1981)

has been limited to the research field, and no use in actual engineering has been found until now.

Auxiliary Ship Movement Methods

Auxiliary ship movement methods aim to enhance the motion of the icebreaker in one or two degrees of freedom, usually the roll and pitch motions, in order to get rid of trapped rapidly. Correspondingly the high-speed rolling and pitching systems are developed. Sometimes

the former is also known as high-speed heeling systems. Both could also collectively be named as tilting technology (Harbron 1983). Most common methods to achieve this goal are to adjust the ballast water.

The method by adjusting ballast water to achieve pitch motion is widely used for the continuous icebreaking mode of icebreaker. The bow of the icebreaker is designed into a special shape, and ballast tanks are equipped at the stem and stern, respectively. Ballast water is firstly adjusted to stern so that the icebreaker trims by

stern and the bow rides on the ice. Usually the weight of ship bow can crush ice. If not, ballast water is adjusted to stem to add the weight of ship on the ice until the ice is crushed.

High-speed heeling system has similar working principle to pitching system. The only different thing may be that the former is usually adopted to prevent the hull from being trapped or frozen, while the latter for continuous icebreaking mode. The working principle of high-speed heeling system is plotted in Fig. 2, where two water tanks are arranged on both sides of the hull. Ballast water loads are continuously transferred between both sides of the tanks, so the hull swings back and forth continuously as a result. In this way, the ship can get rid of the frictional obstacles of the ice on both sides of the hull, thus getting out of trouble. The high-speed heeling system, also known as the active shake system, can be seen as a kind of special anti-heeling system. Different from the general ballast water transfer system, the purpose of this system is to be unbalanced in a faster speed. Therefore, compared to the general system, the pump flow is much larger and the piping and valves are bigger. There are many ballast water transfer technologies, including gravity type, water pump-driven type, and pneumatic type. Each has its own advantages and disadvantages, and they are often used in combination. In the design stage, one needs to consider comprehensively and selects one or several combinations according to the actual demand, thus to achieve the best effect of ballast water adjustment.

Auxiliary Medium Methods

The auxiliary medium icebreaking method is to decrease the resistance between the hull and the ice by adding extra substances between them. In this way the icebreaker can break ice more efficiently. The media can be low friction coatings, which reduces the friction between the hull and the ice directly. The most successful low friction coatings until now may be unsolvated polyurethane and epoxy (Calabrses et al. 1976; Alliston 1985). On the other hand, the media can also be high-pressure water flow, bubbles, and/or steam water mixture, which is the auxiliary medium method we usually refer to. High-pressure compressed water, gas, or water vapor mixture is injected through a number of nozzles arranged on the hull below the waterline. In this way, a low-resistant film is formed between the hull and the ice, which reduces the friction force on the hull. Although the medium differs, the principles are similar. Here we take bubbler system as the example.

Because of the low density of air, bubble drag reduction on ships in open water has been proposed and studied for a long time (Madavan 1985). Similarly, this idea is also used and extended for icebreaker. One of the most representative systems was invented by Wartsila in 1967 and was widely applied to icebreakers in the 1970s, which was called Wartsila Air Bubbling System (WABS) (Parksvangen et al. 1971; Segercrantz 1989), as

Auxiliary Icebreaking

Methods, Fig. 2 The principle of the high-speed heeling system (Yang and Ma 2010)

Auxiliary Icebreaking Methods, Fig. 3 The principle of the air bubble system (Segercrantz 1989)

shown in Fig. 3. The main principle of the system is that the compressed air is ejected from the hole on the lower part of the hull. The rising air bubbles push the broken ice away, thus reducing the friction between the hull and the ice and improving the icebreaking performance of the ship. The icebreaking performance of the ship equipped with the bubble-assisted icebreaking system was studied by using both the scale model and the prototype icebreaker. The results showed that the bubble-assisted icebreaking system could save the power of the icebreaker in the ice-covered zone efficiently and the maximum energy-saving efficiency could reach about 30% (Major 1977; Goodwin 1980; Vance 1980). This technology was also applied to the nuclear-powered heavy icebreaker 50 Let Pobedy, as shown in Fig. 4, which was commissioned in Russia in 2007. The bottom of the ship was equipped with a bubble-assisted icebreaking system that produced $24 \text{ m}^3/\text{s}$ of air bubbles in a region of 9 m deep underwater to assist in icebreaking operations (Zhang et al. 2017).

Additional Floating-Body Methods

Compared with the methods above, additional floating-body technologies can be quite complex. It usually has two distinct characteristics: one is that an auxiliary equipment needs to be installed on a floating body outside the hull and the other is the additional floating body has independent function relative to the main hull. For example, the explosive icebreaking method requires a barge to be equipped with an explosive tank with a mixture of compressed air and hydrocarbon fuel. The barge will be placed under the ice. When the mixture explodes, the open-cell structure on the box will instantaneously release the high-pressure gas and destroy the ice above, thus improving the icebreaking efficiency.

Another typical example is air cushion icebreaking platform or vehicle, which is not limited by draft and can break ice in both deep and shallow waters. At present, countries such as the United States, Canada, Russia, and Finland have

Auxiliary Icebreaking Methods, Fig. 4 Nuclear-powered icebreaker: 50 Let Pobedy (from https://en.wikipedia.org/wiki/50_Let_Pobedy#/media/File:50letPob_pole.JPG)

Auxiliary Icebreaking Methods, Fig. 5 Icebreaking ship of the Canadian Coast Guard: CCGS Sipu Muin (from <https://inter-j01.dfo-mpo.gc.ca/fdat/vessels/98>)

used air cushion platforms and hovercrafts in icebreaking engineering applications, and the icebreaking effect is satisfactory (Hinchey and Colbourne 1995; Whitten et al. 1986). Figure 5 provides the picture of an air cushion icebreaking

vehicle CCGS Sipu Muin of Canada. The icebreaking principles of hovercraft can be divided into low-speed mode and high-speed mode. In low-speed operation conditions, the air cushion pressure causes the water surface below

Auxiliary Icebreaking Methods, Fig. 6 Sketch of air cushion vehicle icebreaking

the ice layer to depress, as shown in Fig. 6. The simplified force model of the ice layer can be seen as a cantilever beam model as a result. When the stress of the ice layer is larger than its allowable stress, the ice will be fractured (Muller 1979; Mellor 1980). In the case of high speed, the hovercraft relies on the wave making on the ice surface to break ice. When the hovercraft moves at a critical speed, the energy of the air cushion vessel exerted to the ice cannot be radiated out. Therefore, under the continuous action of the air cushion vessel, the energy accumulates incessantly, and the amplitude of the fluctuating deformation of the ice layer increases, which eventually leads to the fracture of the ice layer due to the internal bending stress over its yield limit (Buck and Pritchett 1978; Buck et al. 1978).

In conclusion, auxiliary icebreaking methods or technologies have been reviewed and classified roughly. Here we need to clarify that auxiliary icebreaking technology is developing rapidly, so the classification will be advanced with time.

Beaching

Haiming Zhu and Zunfeng Du
Department of Naval Architecture and Ocean Engineering, School of Civil Engineering, Tianjin University, Tianjin, China

Definition

Beaching, as a shipbreaking method, generally refers to dismantling ships at grounded condition in intertidal zones. In this method, a ship is

emptied of cargo and ballast, then driven to coast on a high magnitude tide, and stranded on the beach. The workers access the vessel at low tide and start scrapping for recycling materials.

Scientific Fundamentals

History

Until the 1960s, shipbreaking activities mainly took place in industrialized countries and were conducted off the beach (FIDH 2002). The origin of the beaching can be traced to a Greek ship stranded accidentally on the beach of Sitakunda, Chittagong, during a cyclone in 1960. The vessel could not be refloated and so remained there for several years. In 1965, in East Pakistan, the then Chittagong Steel House bought the ship and had it scrapped on beach. From the early 1980s, the global shipbreaking activities started migrating to South Asian to increase profit (FIDH 2002). The industry developed rapidly in India, Bangladesh, and Pakistan where dismantling was exclusively accomplished on beaches (Yujuico 2014). In the recent years, beaching has become the most commonly used method for shipbreaking worldwide. About two-thirds of the end-of-life ships around the globe are dismantled by beaching each year.

The Layout of the Yards

Taking the beach of Chittagong shipbreaking yard as an example, the beach is generally divided up into

several plots about 60 m wide and up to 90 to 160 m deep. Infrastructure is minimal. It may consist of office building, few heavy-duty winches, vehicle-mounted cranes, and some walls between plots if preferred. Some temporary storage facilities and areas on concrete or steel bases usually exist. More sophisticated operations may have extensive offices, storage areas, and concrete areas within the facility. And even large separate secondary operations areas are on the shore behind the facility, which might include asbestos treatment areas, materials handling areas, medical facilities, shower room, labor shelter, and messing. Moreover, they have their own fire service and hospitals as well as a large and useful training facility on the hill overlooking the beach. The surroundings are typically made up of worker's houses as well as shops reselling the items that come from the ship.

The Process of Beaching

The following passages explain the typical process of beaching in Bangladesh (Hossain and Islam 2006). The process in India and Pakistan is about the same (Deshpande et al. 2013; Ahmed and Siddiqui 2013).

1. Firstly, the ship is anchored in international waters off the coast. The ship will then be inspected, checked, and made gas-free. After the administrative formalities are completed, the ship will obtain a permission to enter territorial waters for beaching. The ship has to wait until the tide condition is ideal for performing beaching. Usually no pre-cleaning of the ships is required for entering the shipbreaking area.
2. When the tide is high, the ship will be driven to the beach by own propulsion power. Usually workers would set up a big colored flag for guidance. After the tide drops, the ship will be lying stable on its flat bottom. The ship must be placed in this exact position and come to ground as high up on the beach as possible to facilitate dismantling operations. If the ships don't make it to the beach and are stranded on the mudflats, they are pulled higher with chains or heavy steel wire hawsers at the next suitable tide after being made lighter. Beaching has a crucial impact on the final cost. The time needed for dismantling can be doubled, if the beaching operation is not successful.
3. After the ship is grounded, the workers start removing items and cutting the vessel into large parts using blowtorches. The parts will drop down to the mudflats and be progressively dragged to the dry part of the shore by winches. Though the machinery does the main job, a large number of workers are engaged to help dragging the parts.
4. Another group of cutters, helpers, and workers start cutting the dragged parts of the ship into trackable parts as per order of the purchasers. The steel is often cut up into around 2×4 m pieces (usual practice) and then sold for cold rolling. Although it may also be cut into inch thick square bars using hydraulic shears and used directly for reenforcing concrete or similar materials, those plates, frames, bars, girder, stiffener, longitudinal, etc. are also used in local ship building or repair industry.
5. The unskilled workers carry metal plates, metal bars, or pipes on their heads or shoulders, then pile up metal plates in stack yards, or load them on trucks. The supervisors control the group of workers; the onlooker guides them and helps them in piling up the heavy metal plates in stacks.
6. Heavy equipment like boilers, motors, capstan stocking, etc. are carried to stack yards by moving crane. The valuable components (e.g., small motors and pumps, generator, navigation equipment, life-saving equipment, furniture, electrical cables, utensils, etc.) are dismantled and sold to secondhand market. It needs 5–6 months to dismantle a typical cargo ship.

Hazards of Beaching

End-of-life ships contain a great amount of hazardous materials. Depending on the size and function of the ship, scrapped ships have an unladen weight of between 5000 and 40,000 tons (the average being 13,000+), 95% of which is steel, coated with between 10 and 100 tons of paint

containing lead, cadmium, organotins, arsenic, zinc, and chromium. Ships also contain a wide range of other hazardous wastes, sealants containing PCBs, up to 7.5 tons of various types of asbestos, and thousands of liters of oil (engine oil, bilge oil, hydraulic and lubricant oils, and grease). Tankers additionally hold up to 1000 cubic meters of residual oil. Most of these materials have been defined as hazardous waste under the Basel Convention (Hossain and Islam 2006).

The breaking process would release those materials, threatening the health of the workers and the ambient environment. The problem is more serious when the ships are dismantled on beach other than in the dock, because hardly any protection measures will be taken.

Impact on Intertidal Sediments and Soils

In shipbreaking areas, various refuse and disposable materials are dropped or stacked haphazardly on the seashore. The hazardous materials are accumulated and get mixed in the soil. Those materials are mainly metal fragments and rust (particularly iron). It accelerates the amount of shore erosion and increases the turbidity of seawater and sediments in the area (Hossain and Islam 2006). Trace metals can be found in the sediments. Accumulation levels of Cr, Zn, As, Pd, and Cd are higher than recommended values of unpolluted sediments (Hasan et al. 2013a). There are on average 81 mg of small plastic fragments per kg of sediment. They do not degrade easily and hence pose a threat to the environment and marine ecosystems (Reddy et al. 2006).

Impact on Seawater

Ship scrapping activities pollute the seawater environment in the coastal area. Seawater is strongly polluted by Fe, Pd, and Hg, moderately by Mn and Al, and slightly by Pb and Cd. Groundwater is also polluted, strongly by Fe, Pb, and Hg, moderately by Mn and Al, and slightly by As (Hasan et al. 2013b). Toxic concentration of ammonia and marine organisms found in seawater had an increase in PH levels. Critical concentration of dissolved oxygen (DO) and higher biochemical oxygen demand

(BOD) were found with an abundance of floatable materials (grease balls and oil films) in the seawater (Hossain and Islam 2006).

Impact on Biodiversity

Shipbreaking activities contaminate the coastal soil and seawater environment mainly through the discharge of ammonia, burned oil spillage, floatable grease balls, metal rust (iron), and various other disposable refuse materials together with high turbidity of seawater. The high PH of the seawater and soil observed may be due to the addition of ammonia, oils, and lubricants. High turbidity of water can cause a decrease in the concentration of DO and substantially increase the BOD. Furthermore, oil spilling may cause serious damage by reduction of light intensity, inhibiting the exchange of oxygen and carbon dioxide across the air-seawater interface, and by acute toxicity. As a result, the growth and abundance of marine organisms especially plankton and fishes may seriously be affected. Indiscriminate expansion of shipbreaking activities poses a real threat to the coastal intertidal zone and its habitat (Hossain and Islam 2006).

Worker Rights Violation

In the majority of the shipyards in developing countries, workers are being deprived of their rights. They work under risky conditions but have no access to safety equipment, job security, or a living wage.

Shipbreaking carries a very real risk to life. By any standards, the demolition of ships is a dirty and dangerous occupation. The hazards linked to shipbreaking broadly fall into two categories: intoxication by dangerous substances and accidents on the plots. Explosions of leftover gas and fumes in the tanks are the prime cause of accidents in the yards. Another major cause of accidents is workers falling from the ships (which are up to 70 m high) as they are working with no safety harness. Other sources of accidents include workers being crushed by falling steel beams and plates and electric shocks.

Workers are not aware of hazards to which they are exposed. The overwhelming majority of

workers wear no protective gear, and many of them work barefoot. There is hardly any testing system for the use of cranes, lifting machinery, or a motorized pulley. The yards reuse ropes and chains recovered from the broken ships without testing and examining their strength. There is no marking system of loading capacity of the chains of cranes and other lifting machineries. Gas cutters and their helpers cut steel plates almost around the clock without eye protection. This leaves their eyes vulnerable to effects of welding. They do not wear a uniform and most don't have access to gloves and boots. Those that are "unskilled" carry truckable pieces of iron sheets on their shoulders, and there are no weight limits to the sheets they carry. Usually, these workers carry weights far above the limit prescribed in the Factories Act and Factories Rules. Besides, the beaches are strewn with chemicals and toxic substances, small pieces of pointed and sharp iron splinters causing injuries. Workers enter into the areas without wearing or using any protective equipment.

When there is an injury, some immediate treatment may be given, but there is no long-term treatment for those who have a long-term or permanent injury. In terms of compensation, only a nominal amount of compensation given and often only when there is public pressure. When a worker becomes disabled by a major accident, he gets a maximum of 10 to 15 thousand taka (1 USD = 71 taka) and forced back to his home district. In most cases a worker will only get transportation costs to go back to their home district. When a worker killed in an accident, the contractor, who is responsible for the workers, will only pay the costs of sending the body back to the victim's family and arranging for their burial. So far, the treatment and compensation problems of workers have not been well resolved.

Applications

Beaching activities mainly took place in India, Bangladesh, and Pakistan. Table 1 shows the

Beaching, Table 1 The number of ships dismantled by beaching in 2015–2017

Country	2015	2016	2017
India	194 (25%)	305 (35.4%)	239 (28.6%)

Ships dismantled worldwide	768	862	835

application condition of beaching in 2015–2017 (NGO Shipbreaking Platform 2016, 2017, 2018).

The main reasons for the phenomenon including (FIDH 2002):

1. Shipbreaking industry requires cheap human man power, which is available in developing countries with large population, such as India, Bangladesh, and Pakistan. In these nations, millions of people are in the state of poverty, providing abundant cheap labor.
2. The coastal areas of the shipbreaking yards have wide and gently sloping sand tidal beaches, making it possible to drive ships onshore as far up the beach as possible at spring tides and dismantle the ships at grounded condition.
3. In most countries, beaching had already been prohibited for environmental protection and occupational health and safety concerns. However, regulations and standards are loose in India, Bangladesh (Alam and Faruque 2014), and Pakistan compared to other ship recycling nations.
4. The convenient location of the Indian subcontinent, the suitable climate, and domestic market for scrapped steel are also factors that promote the prosperity.

The shipbreaking yards that utilize beaching method concentrated in the following regions:

1. The Alang-Sosiya beach is in the State of Gujarat on the west coast of India. This region has one of the longest continental shelves and the second highest tide port in the world, making it an ideal site for beaching (Patel et al. 2013). The Alang-Sosiya shipbreaking yard is considered the world's largest of its kind. According to statistics, in 2012, there were 171 yards in the region (92 in Alang, 79 in Sosiya) with about 60,000 workers, handling around 350 ships yearly (Deshpande et al. 2012).
2. The shipbreaking yards in Chittagong stretch about 20 km along the coast of Sitakunda Thana region (Gregson et al. 2012), a well-known shipbreaking area which is about 20 km northwest of Chittagong. Chittagong shipbreaking yard was the largest shipbreaking yard in the world from 2004 to 2008. Today, it takes the second place in the industry.
3. Gadani shipbreaking yard located across a 10-km-long beach at Gadani, Pakistan, about 50 km northwest of Karachi. In the 1980s, Gadani was the largest shipbreaking yard in the world with more than 30,000 direct employees. Gadani ranks as the world's third largest shipbreaking yard after Alang-Sosiya and Chittagong in terms of volume.

Bearing Capacity of Spudcans

Long Yu and Heyue Zhang
Dalian University of Technology, Dalian,
China

Synonyms

Footing; Foundation

Definition

Spudcan is the term used for the base cones on mobile-drilling jack-up platform. The spudcans are the inverted cones mounted at the base of the jack-up which provide support for the stability of jack-up rig when deployed into ocean-bed systems.

Bearing Capacity of Spudcans, Fig. 1 A typical jack-up unit (<https://cn.bing.com/images/search?q=jack-up&FORM=HDRSC2>)

Jack-up units are self-elevating mobile platforms which are used extensively in offshore oil and gas industry.

Bearing capacity is the ability of soil to safely carry the pressure placed on the soil from any engineered structure without undergoing a shear failure with accompanying large settlements (Lambe and Whitman 2008).

Scientific Fundamentals

Jack-Up Unit

A typical jack-up unit (as shown in Fig. 1) consists of a floatable platform (hull) and three independent retractable truss-work legs each resting on a spudcan footing.

Figure 2 shows the operation sequence of a jack-up unit. Once a jack-up unit is towed to site, its installation begins by lowering the legs to the seabed and pushing the spudcans into the

Bearing Capacity of Spudcans, Fig. 2 The operation sequence of a jack-up unit (Kong 2011) (a) Towing to site (b) Installation and preloading (c) Operating (d) Removal

soil and then rising the hull over the water. Then preloading can be achieved by pumping water into the hull. The preloading makes the spudcan penetrate deeper to provide more resistances. After preloading, the water is pumped out and the spudcan bearing capacity has some reservation. After all the work of the jack-up has finished, it is removed from the site by retracting the legs from the seabed (Kong 2011).

The Typical Geometry of Spudcans

The spudcans are of inverted cone shape commonly in polygonal or circular shape in plane. In the early days, the diameter of spudcans was within 5–10 m (Young et al. 1984). The shape and size of spudcans evolved for the operation of jack-up unit in deeper waters, and modern spudcans are typically between 10 and 20 m in diameter. Along with the increasing demands of operating on very soft soils, the footings become larger and flatter at base, such as HYSY944 (Hai-bo 2016) (as shown in Fig. 3c). Typical spudcan designs are illustrated in Fig. 3.

Alternative Foundations

In some complex environment conditions, such as penetrating on layered soil, especially on the sand overlying clay soil, the use of fusiform spudcan is

limited for its high risk of punch-through failure. To mitigate the punch-through failure potential of spudcan foundations for jack-up rigs on layered soils, skirted footings (Fig. 4a) are increasingly being considered (Yu et al. 2010). The skirted foundation is a flat spudcan foundation fitted with a thin skirt at the circumference. It appears like an upturned bucket.

The whole drilling processes of installation and extraction of the spudcan will leave a permanent seabed depression at each footing site, which is referred to as a footprint. With the extensive and more frequent use of jack-up units, the existence of footprints is common. Now jack-up units often have to be installed near or into existing footprints in order to drill, and it can lead to significant loss of time, cost implications, risks to adjacent structures, and potential injury to personnel. Jun et al. (2016) present a novel spudcan with six evenly spaced holes at the base to ease spudcan-footprint interaction issues as shown in Fig. 4b.

The Bearing Capacity of Shallow Footing

When a load is applied on a limited portion of the surface of a soil, the surface settles. The relation between the settlement and the average load per unit of area may be represented by a settlement curve (Fig. 5). If the soil is fairly dense or stiff, the

Bearing Capacity of Spudcans, Fig. 5 Relation between intensity of load and settlement of a footing on C_1 dense or stiff and C_2 loose or soft soil (Terzaghi et al. 1995)

settlement curve is similar to curve C_1 . The abscissa of the vertical tangent to the curve represents the bearing capacity of the soil. If the soil is loose or fairly soft, the settlement curve may be similar to C_2 , and the bearing capacity is not always well defined. The bearing capacity of

such soils is commonly assumed to be equal to the abscissa of the point at which the settlement curve becomes steep and straight.

In practice, loads are transmitted to the soil by means of footings, as shown in Fig. 6. The footings may be continuous, having a long rectangular shape, or they may be spread footings, which are usually square or circular. The distance from the level of the ground surface to the base of the footing is known as the depth of foundation D . A footing that has a width B equal to or greater than D is considered a shallow footing.

For purpose of analysis, the actual situation shown in Fig. 6a is usually replaced by the situation shown in Fig. 6b: the soil above the base of the footing is replaced by a uniform surcharge of intensity $q = \gamma D$, where γ is the unit weight of the soil and D is the depth of the base of the footing below ground surface. The effect of the weight of the soil above the footing base is thus taken into consideration, and the shear resistance of the soil is neglected.

The approximate value of the bearing capacity can be written as the sum of the three terms: the

Bearing Capacity of Spudcans, Fig. 6 Shallow footing under a vertical load (Terzaghi et al. 1995) (a) Actual situation (b) Assumed situation

unit weight of the soil, the surcharge, and the cohesion of soil (only for clay soil) (Terzaghi et al. 1995):

$$q_u = cN_c s_c d_c + qN_q s_q d_q + \frac{1}{2} \gamma B N_\gamma s_\gamma d_\gamma$$

In which N_c and N_q are the bearing capacity factors with respect to cohesion and surcharge, respectively. The surcharge is represented by the weight per unit area γD of the soil surrounding the footing. The bearing capacity factor N_γ accounts for the influence of the weight of the soil. All the bearing capacity factors are dimensionless quantities depending only on ϕ' . s_c, s_q, s_γ are the correction factors corresponding to the footing shape. d_c, d_q, d_γ are the correction factors corresponding to the embedment depth of footing. B is the diameter of a circular footing or the width of a strip footing.

The Analysis Model of the Bearing Capacity of a Spudcan

For conventional bearing capacity analyses, the spudcan is often modeled as a flat circular footing. The equivalent diameter is determined from the area of the actual spudcan cross section in contact with the seabed surface, or where the spudcan is fully embedded, from the largest cross-sectional area. Bearing capacity analyses are then performed for this circular foundation at the depth (D) of the maximum cross-sectional area in contact with the soil (Fig. 7). The depth of simplified spudcan penetration is usually defined as the distance from the spudcan bottom to the mudline (SNAME 2008).

The Soil Parameters

Where geotechnical analyses are performed, they should be based on geotechnical data obtained from a site investigation incorporating soil sampling and/or in situ testing. Uncertainties regarding the geotechnical data should be properly reflected in the interpretation and reporting of analyses for which the data are used.

Key Applications

In determining whether a jack-up unit may be safely used at a particular site, two separate analyses of foundation bearing capacity must generally be undertaken:

- Prediction of footing penetration during preloading (vertical load only)
- Assessing of footing stability under design storm conditions (combined vertical, horizontal, and moment loading)

Prediction of Footing Penetration During Preloading

The Influence of Soil Backflow

During penetration, the possibility of soil backflow over the footing should be considered when computing bearing capacity. In very soft clays, complete backflow may occur, whereas in firm to stiff clays and granular materials, where limited footing penetration may be expected, the

Bearing Capacity of Spudcans, Fig. 7 Spudcan foundation model (SNAME 2008)

significance of backflow diminishes. Backflow in clay may be assumed not to occur if:

$$D \leq \frac{Nc_s}{\gamma'}$$

In this case, c_s is taken as the average undrained cohesive shear strength over the depth of the excavation, N is a stability factor, and γ' is the submerged unit weight of the soil. Conservative stability factors in uniform clays, as a function of excavation depth and diameter, are summarized in Fig. 8. For spudcan penetration analyses, it is recommended that conservative criteria are used and the excavation depth be considered as the depth to the maximum spudcan bearing area.

For the conservative evaluation of the hole backflow, the stability factors of Meyerhof (1972) are used. However, for normally

consolidated clay profiles, the Britto and Kusakabe (1983) curve may be more appropriate.

It should be noted that the expression above is based on static hole stability. In reality, during penetration of the spudcan, the soil will probably flow along the spudcan upward onto the top of the spudcan. Hence, the hole stability derived from the expression may be too optimistic.

Penetration in Clays

The ultimate vertical bearing capacity of a foundation in clay (undrained failure in clay, $\phi = 0$) at a specific depth can be expressed by:

$$F_V = (cN_{cs}d_c + q')A$$

In which c is the undrained cohesive shear strength at $D + B/4$ below mudline, and B is the effective spudcan diameter at uppermost part of

Bearing Capacity of Spudcans,

Fig. 8 Stability factors for cylindrical excavations (SNAME 2008)

bearing area in contact with the soil. q' is the effective overburden pressure at depth D of maximum bearing area ($q' = \gamma' D$). For circular footing, the value of N_c is taken as 5.14.

The maximum preload is equal to the ultimate vertical bearing capacity, F_V , taking into account the effect of backflow, $F'_0 A$, and the effective weight of the soil replaced by the spudcan, $\gamma' V$, i.e.:

$$VL_0 = F_V - F'_0 A + \gamma' V$$

In which F'_0 is the effective overburden pressure due to backflow at depth of uppermost part of the bearing area. The terms $-F'_0 A + \gamma' V$ should always be considered together. Because when the soil flows back during penetration, the backflow soil covers on the top of the footing, which reduces the maximum preload VL_0 . At the same time, the footing is fully buried in soil and the footing subjected to an up-floating force $\gamma' V$, which increases the maximum preload VL_0 .

The bearing capacity formula given above has been empirically derived for surface foundations and does not account for foundation roughness, shape (conical for most spudcans), or the effects of increased shear strength with depth.

Penetration in Silica Sands

The ultimate vertical bearing capacity of a circular footing resting in silica sand or other granular

material ($c = 0, \phi \neq 0$) can be computed by the following equation:

$$F_V = (0.5\gamma' B N_\gamma s_\gamma d_\gamma + q' N_q s_q d_q) A$$

The maximum preload is equal to the ultimate vertical bearing capacity, F_V , taking into account the effect of backflow, $F'_0 A$, and the effective weight of the soil replaced by the spudcan, $\gamma' V$, i.e.:

$$VL_0 = F_V - F'_0 A + \gamma' V$$

Footing penetrations in a thick layer of clean silica sand are usually minimal with the maximum diameter of the spudcan rarely coming into contact with the soil. It is therefore not usual to consider the effects of soil backflow in this situation.

Typically observed load-penetration data for large-diameter spudcans suggest that reduced friction angles may be applicable for this analysis method. To account for this, it is recommended that laboratory triaxial ϕ test values should be reduced by 5° for the prediction of large-diameter footing penetrations in silica sands, i.e., $\phi_{\text{design}} = \phi_{\text{triaxial}} - 5^\circ$.

For spudcans on sand, the effects of cyclic loading may be to either increase or decrease the pore water pressure. Positive excess pore water pressure will weaken the soil and in severe cases

may cause partial fluidization. Negative excess pore water pressures may temporarily strengthen the soil. Approximate methods are available for the assessment of excess pore water pressure development and associated foundation settlement.

Penetration in Silts

For silts, it is recommended that upper and lower bound analyses for drained and undrained conditions are performed to determine the range of penetrations. The upper bound solution is modeled as a loose sand and the lower bound solution as a soft clay. Cyclic loading may significantly affect the bearing capacity of silts.

Cyclic loads imposed in silty fine sands/silt foundations may cause liquefaction due to the generation of excess pore water pressures. In this situation foundation settlements would be anticipated. Conservative assessments of reduced bearing capacities and increased settlements should be conducted as appropriate.

Penetration in Carbonate Sands

Penetrations in carbonate sands are highly unpredictable and may be minimal in strongly cemented materials or large, in uncemented materials. Extreme care should be exercised when operating in these materials.

Relatively large footing penetrations have been reported for uncemented carbonate materials despite high laboratory friction angles (Dutt and Ingram 1988). This may be attributed to either the high compressibility of these materials or low shear strengths due to high voids ratio and a collapsible structure.

The leg penetration is governed by both strength and deformation characteristics of foundation soils. The compressibility of carbonate sands is relatively higher than for silica sands. Hence, greater penetrations should be expected for carbonate sands relative to silica sands despite the similar or even higher laboratory friction angles.

The predictions of footing penetrations in carbonate sands are likely to be performed to a lower degree of accuracy compared with those for silica sands. The conventional method is to use the plasticity-based formulation for bearing capacity of shallow foundations in sand. However, friction angles to be used in the formulae should be

considerably smaller than laboratory values to account (in an artificial manner) for the soil behavior.

Penetration in Layered Soils

Three basically different foundation failure mechanisms are considered in spudcan predictions in layered soils:

1. General shear
2. Squeezing
3. Punch-through

The first failure mechanism occurs if soil strengths of subsequent layers do not vary significantly. Thus an average soil strength (either c or ϕ) can be determined below the footing. The footing penetration versus foundation capacity relationship is then generated using criteria from the formulae mentioned above. The punch-through condition concerns a potentially dangerous situation where a strong layer overlies a weak layer and hence a small additional spudcan penetration may be associated with a significant reduction in bearing capacity (Liu et al. 2005; Yu et al. 2012). But it is complicated and no good solution has been proposed. In this section, criteria for squeezing are given below.

On a soft clay subject to squeezing overlaying a significantly stronger layer (Fig. 9), the ultimate vertical bearing capacity of a footing given by Meyerhof (1972) is:

For no backflow conditions:

$$F_V = A \left\{ \left(a + \frac{bB}{T} + \frac{1.2D}{B} \right) c + q' \right\} \\ \geq A \{ c N_{cs} d_c + q' \}$$

and for full backflow conditions:

$$F_V = A \left\{ \left(a + \frac{bB}{T} + \frac{1.2D}{B} \right) c \right\} + \gamma' V \\ \geq A \{ c N_{cs} d_c \} + \gamma' V$$

where the following squeezing factors are recommended: $a = 5.00$, $b = 0.33$, and c refers to the undrained shear strength of the soft clay

Bearing Capacity of Spudcans, Fig. 9 The failure mechanism of squeezing

B

layer. T is the thickness of the soft clay beneath the bottom of footing.

It is noted that the lower bound foundation capacity is given by general failure in the clay layer and that squeezing occurs when $B \geq 3.45T$ ($1 + 1.1D/B$). The upper bound capacity (for $T \ll B$) is determined by the ultimate bearing capacity of the underlying strong soil layer.

For a squeezing clay layer, the resistance on the footing cannot become larger than the resistance of the layer underneath the soft clay layer. Thus, there is a limit to the squeezing process.

Assessing of Footing Stability Under Combined Vertical, Horizontal, and Moment Loading

Combined Loading: Vertical Load and Moment ($H = 0$)

Bearing capacity under combined loads V and M has traditionally been studied as the statically equivalent problem of an eccentric vertical load. This interpretation led Meyerhof (1953) to the concept of effective area, in which the eccentric vertical load is assumed to act centrally on a strip foundation of reduced area, as shown in Fig. 10b. Brinch Hansen (1970) was the first to propose that eccentrically loaded circular footing be treated as shown in Fig. 10c.

The bearing capacity interaction for a circular footing on clay is:

$$\frac{V}{V_0} = \left(\frac{\pi + 2 + (B'/L')}{\pi + 3} \right) \cdot \frac{A'}{A}$$

where V_0 is the bearing capacity under central vertical loading and A is the gross footing area πR^2 .

Combined Loading: Vertical Load and Horizontal Load ($M = 0$)

This loading combination is statically equivalent to a single load acting at the footing center line, inclined at an angle to the vertical (Fig. 11).

Penetration in Sand

The general ultimate vertical/horizontal bearing capacity envelope for jack-up footings in sand is as follows:

$$F_{VH} = (0.5\gamma'BN_\gamma s_\gamma d_\gamma i_\gamma + q'N_q s_q d_q i_q)A$$

In which F_{VH} is the vertical foundation capacity in combination with horizontal load, and i_γ and i_q are inclination factors which consider the influence of horizontal force. Substituting for i_γ and i_q , the appropriate relationship may be written for generation of the foundation capacity for combined vertical and horizontal loading as:

$$F_{VH} = \left(0.5\gamma'BN_\gamma s_\gamma d_\gamma [1 - (F_H/F_{VH})^*]^{m+1} + q'N_q s_q d_q [1 - (F_H/F_{VH})^*]^m \right) A$$

This may be solved by the use of assumed values for (F_H/F_{VH}) designated $(F_H/F_{VH})^*$. For example, use $(F_H/F_{VH})^* = 0, 0.04, 0.08, 0.12$, etc. For these values corresponding F_{VH} values may be determined. The correct F_H values may then be determined as F_{VH} and $(F_H/F_{VH})^*$ are known, e.g., for:

$$(F_H/F_{VH})^* = 0.12, F_H = 0.12F_{VH}^*$$

The corrected horizontal capacity, F_H , may then be given as:

(a) The equivalent model for combined V and M loads

(b) Effective area concept: strip footing (Meyerhof, 1953)

(c) Effective area concept: strip footing (Brinch Hansen, 1970)

Bearing Capacity of Spudcans, Fig. 10 Combined vertical load and moment (Martin 1994) (a) The equivalent model for combined V and M loads (b) Effective area

concept: strip footing (Meyerhof 1953) (c) Effective area concept: strip footing (Brinch Hansen 1970)

Bearing Capacity of Spudcans, Fig. 11 The equivalent model for combined V and M loads (Martin 1994)

$$F_H = F_H^* + 0.5\gamma'(k_p - k_a)(h_1 + h_2)A_S$$

In which k_a is the active earth pressure coefficient, for the case of $c = 0$, $k_a = \tan^2(45 - \phi/2)$.

Accordingly k_p is the passive earth pressure coefficient and $k_p = 1/k_a$. h_1 is the embedment depth to the uppermost part of the spudcan (if not fully embedded $h_1 = 0$), and h_2 is spudcan bottom

embedment depth. A_S is spudcan laterally projected embedded area.

The sliding capacity envelope of a footing in sand is given by:

$$F_H = F_{VH} \tan \delta + 0.5\gamma'(k_p - k_a)(h_1 + h_2)A_S$$

where δ is the steel/soil friction angle which for a flat plate, $\delta = \phi - 5^\circ$, and for a rough surfaced conically shaped spudcan, $\delta = \phi$.

Penetration in Clay

The general equation for the horizontal and vertical bearing capacity envelopes for footings in clay is as follows:

$$F_{VH} = (cN_c s_c d_c i_c + q'N_q s_q d_q i_q)A$$

Substituting for the inclination factors for a circular footing, the equation may be written as:

$$F_{VH} = \left\{ cN_c s_c d_c \left[1 - \left(1.5 F_H^* / c_{AN_c} \right) \right] + q'N_q s_q d_q \left(1 - F_H^* / F_{VH} \right)^{1.5} \right\} A$$

The ultimate bearing capacity envelope under inclined loading may be determined by substituting values of F_{VH} and solving for F_H^* ; F_H may then be given as:

$$F_H = F_H^* + (c_0 + c_1)A_S$$

In which c_0 is undrained cohesive shear strength at maximum bearing area (D below mudline) and c_1 is undrained cohesive shear strength at spudcan tip. When $0 \leq Q_V \leq 0.5F_V$, the sliding capacity in clay may be conservatively assumed constant, determined by $F_H = Ac_0 + (c_0 + c_1)A_S$.

Penetration on Layered Soils

The above formulae can also generally be used to make a conservative estimate of the ultimate $F_{VH} - F_H$ relationship for layered soils by considering failure through the weakest zones in such a soil profile. The bearing capacity of layered soils may be determined using the principles of

limiting equilibrium analysis or the finite element method.

Combined Loading: Vertical, Horizontal, and Moment Loads

This case has usually been approached in the manner first suggested by Meyerhof (1953): an inclined load of magnitude $\sqrt{V^2 + H^2}$ is assumed to act centrally on a reduced foundation area determined by the eccentricity $e = M/V$, as illustrated in Fig. 12.

For shallow embedment for both sand and clay, the yield interaction is defined by the following expression:

$$16 \left[\frac{F_{VHM}}{V_{L0}} \right]^2 \left[1 - \frac{F_{VHM}}{V_{L0}} \right] \left[1 - \frac{F_{VHM}}{V_{L0}} \right] - \left[\frac{F_{HM}}{H_{L0}} \right]^2 \left[\frac{F_M}{M_{L0}} \right]^2 = 0$$

In which F_{VHM} represents vertical foundation capacity in combination with horizontal and moment load; F_{HM} represents horizontal foundation capacity in combination with moment. F_M is the moment capacity of foundation, where V_{L0} is taken to be equal to the vertical spudcan load achieved during preloading and H_{L0} and M_{L0} are defined as follows:

For sand:

$$H_{L0} = 0.12V_{L0}, M_{L0} = 0.075BV_{L0},$$

For clay:

$$H_{L0} = c_0A + (c_0 + c_1)A_S, M_{L0} = 0.1BV_{L0}$$

Note that in the above expression for the yield surface, if a load combination (Q_V, Q_H, Q_M) satisfies the equality, then $(Q_V, Q_H, Q_M) = (F_{VHM}, F_{HM}, F_M)$. The load combination (Q_V, Q_H, Q_M) lies outside the yield surface if the left-hand side is less than zero. Conversely, the load combination lies inside the yield surface if the left-hand side is greater than zero.

Embedded footings in clay achieve greater moment and sliding capacities as compared to shallow penetrations in clay. Figure 13 is an example of 3-D failure envelope of embedded

Bearing Capacity of Spudcans, Fig. 12 The equivalent model for combined V , H , and M loads (Martin 1994) (a) Positive (forward) eccentricity (b) Negative (backward) eccentricity

Bearing Capacity of Spudcans, Fig. 13 A three-dimensional failure envelop for combined loading V , H , and M (Wang et al. 2011) (a) Homogeneous clay (b) NC clay

spudcan in clay. There is no existing data for deeply embedded footings in sand. The application of the yield surface calibrated to shallow penetrations will likely be conservative for the deep penetration case.

Definition

Big data is not a newly developed concept from an evolutionary perspective. Various data warehouses have been created to store huge amount of data, such as weather data, consumption data, and stock index data, ever since the 1990s. During that time, one terabyte was considered as big data, but any numerical definition is expected to be modified over time as the development of collecting, storing, and analyzing data technology (Watson 2014). One important characteristic is

that big data can be loosely defined as data sets with sizes beyond the ability of common statistical software or database management system (Snijders et al. 2012). An alternative approach is to feature big data mainly in 3 Vs – volume, velocity, and variety (Hilbert 2016). In today's digital world, every single thing can be regarded as of generating data, for example, sensors/meters and activity records from electronic devices, social media, business transactions, electronic files, etc.

Overview of Big Data Techniques

Hence, the data process ability is the crucial point for the big data era. The big data process generally consists of data collection, data processing, data cleaning, exploratory data analysis, and modeling and algorithms; see Fig. 1 for flowchart (O'Neil and Schutt 2013).

In addition, the collection and storage of data have little values for practical applications if no methods have been applied for the exploitation of the data, i.e., so-called data analysis. The data analysis is the key to make use of these tremendous databases, which can help to enhance decision-making, provide insight and projection, and support and optimize processes.

Within the field of data analysis, machine learning is one of the promising methods that integrate mathematical technologies with computer systems. They can increase the capability of formulating complex models and algorithms to learn and make projections on data (Koza et al. 1996). Those analytical models allow researchers and engineers to make dependable and repeatable results and decisions; see Fig. 2 (Business Link Solutions). It is used extensively in the development of autonomous vehicles, such as self-driving cars, unmanned ships, speech recognition, information retrieval, credit card fraud, spam detection, product recommendation, medical diagnosis, customer segmentation, etc. Some of the largest online selling companies also use the big data techniques to target the potential customers of their products to boost their business.

Depending on the strategies used in the data analysis process, machine learning is commonly categorized as the following techniques: supervised learning, semi-supervised learning, active learning, unsupervised learning, and reinforcement learning. When using the supervised learning, the existing data contains the desired output and the goal. For example, if one wants to predict a ship's power in terms of the ship's sailing speed, heading, and encountered sea

B

environment, both the predicted target, i.e., a ship's power and the dependent variables, i.e., speed, sea parameters, etc., should be included in the data for supervised learning. This learning technique is to obtain a certain model that describes the relationship between inputs and outputs (also called targets). There are two types of supervised problems. In classification problems, the target outputs are discrete, while regression problems deal with continuous outputs. A typical example of a classification problem is to predict whether incoming mail is spam or not. A regression example is to predict the value of a house given its size, number of rooms, etc. In unsupervised learning the desired outputs are unknown, and the learning algorithm looks for patterns and/or structure in the data. A typical example is a clustering problem like customer segmentation, finding out which customers exhibit similar behavior. In reinforcement learning, the computer/algorithm interacts with a dynamic environment and learns the ideal behavior within a specific context. Some sort of feedback is required during the learning process to obtain this behavior. For example, a computer-controlled playing chess game or autonomous driving often adopts this type of learning. Following are the most common tasks, regression, classification, clustering, multivariate querying, density estimation, dimension reduction, testing, and matching (Christopher 2006).

The most classical outlining framework for approaching machine learning (supervised) is

proposed by Guo (Towards Data Science); the following are the seven systematic steps:

1. Gathering data: for per-collected data, the quantity and quality highly influence how accurate the model and algorithm is.
2. Data preparation: clean the required data (deal with missing values, remove duplicates, normalization, etc.), split into training and evaluation set.
3. Choosing a model: choose the correct models and algorithms for different cases.
4. Training: the aim of this step is to make the prediction correctly; the process is repeated until to an ideal separation.
5. Evaluation: test the model against previous data that has never been used in training, to measure the objective performance of model.
6. Parameter tuning: tuning the parameters to further improve the training, the hyperparameter may include number of training iteration, learning rate, etc.
7. Prediction: use further data to test the model and to assess how the model will perform in the real application.

Big Data Applications in Marine Technology

As stated in Global Marine Technology Trends 2030 report, big data will be one of the most important transformational techniques being

Big Data-Based Decision Support Systems, Fig. 3 Big data analytics are expected to be used in the marine industry (Shenoi et al. 2015)

used in marine technology (commercial shipping, naval, and ocean); see Fig. 3 (Shenoi et al. 2015). The data generated and collected from aerial remote sensing, ship, stations, buoys, and satellites are rapidly growing all over the world. Those tremendous data can be processed and analyzed to provide new knowledge and added values that we never know before in marine industry, which is relatively traditional and slow-moving (Trelleborg Marine System).

This cross technology will introduce the big data-driven innovations to ship design, material performance and inventory, condition monitoring, meteorological and oceanographic projections,

inspection and maintenance, communication and navigations, etc.

Big data support decision-making systems have been widely used in maritime transport. Shipping has taken over 90% of the world trade volume. As the development of sensors, tracking system onboard, and communication techniques between ship and shore, the maritime transport is embracing the digital era (Mirovic et al. 2018). DNV-GL, ClassNK, and major classification societies have set their blueprints in big data, optimizing the decision-making, to lower the fuel consumption and overall cost and ensure the safety (Koga 2015). A classical maritime

Big Data-Based Decision Support Systems, Fig. 4 Data flowchart for ship navigation and performance (Perera and Mo 2016)

Big Data-Based Decision Support Systems, Fig. 5 Shaft power prediction and the corresponding full-scale measurements over the whole navigation campaign (Mao et al. 2016)

transport data flowchart is presented in Fig. 4 (Perera and Mo 2016).

The onboard sensors measure the ship performance, navigation data, and process and transmit to data center, where the recorded data are stored and analyzed. Then the decision support system optimizes and improves the operations and ship management.

For the shipping management, one of the top issues is the ship route plan and optimization, based on the ship fuel consumption estimation. Conventional fuel consumption model contains marine engine configuration, ship resistance, hull and propeller efficiency, etc., which has high uncertainties in the inputs. In order to estimate the ship fuel consumption accurately, the big data technique, more specifically machine learning, has been successfully applied in (Mao et al. 2016) to predict shaft power for a C-class 45000 DWT chemistry tanker; see Fig. 5 (Mao et al. 2016).

Machine learning has shown the capacity to predict ship power and fuel cost with an acceptable discrepancy. In addition, it has the potential for ocean weather prediction and even ship route optimization directly. As more and more organizations are investing and shipping companies are willing to share the data information, big data will become the “oil of the twenty-first century” for the maritime industry, and the shipping will wake up eventually to the new digital era (Marine Digitalization & Communications).

Conservation biology; Conservation of biological diversity

Definition

Biodiversity is “the variety of different forms of life on earth, including the different plants, animals, micro-organisms, the genes they contain and the ecosystem they form” (Rawat and Agarwal 2015). Biodiversity conservation is “about saving life on Earth in all its forms and keeping natural ecosystems functioning and healthy” (Rawat and Agarwal 2015).

Scientific Fundamentals

Three Foundational Elements of Biodiversity Conservation

In 1990, the International Union for the Conservation of Nature (IUCN) identified the conservation of genetic diversity, species diversity, and ecosystem diversity as the three foundational elements of biodiversity conservation (McNeely et al. 1990).

Genetic diversity is “the sum of genetic information and trait contained in the genes of individuals of plants, animals and micro-organisms” (Pearce et al. 1994). Genetic diversity provides the basis for adaptation to environmental change, and such adaptation is the key to the long-term survival of species (Schemske et al. 1994). Preserving high levels of heritable variation and preventing fixation of deleterious alleles are the two primary goals of conservation biologists in their study and application of genetics (Dyke and Lamb 2020).

Species diversity is “the variety of species or the living organisms” (Rawat and Agarwal 2015). There are many different definitions of species. The Most widely employed is the Mayr’s definition that a species is “a group of interbreeding populations that are reproductively isolated from other such groups” (Mayr 1969). As the molecular techniques have developed, people can examine and compare the information of the DNA, chromosomes and gene loci of organisms, the phylogenetic species concept was proposed. According to the phylogenetic species concept, a species represents “a group of organisms with an assumed or determined common ancestral lineage whose genetic similarities, differences, and distances are distinguishable from other such groups” (Dyke and Lamb 2020). Mayr’s definition is applied to organisms that reproduce sexually and the phylogenetic species concept is applied to any organism that has genes.

Ecosystem diversity deals with the variety of habitats, biotic communities, and ecological processes in the biosphere and its overall impact on human existence and the environment (Pearce et al. 1994). Diversity of ecosystem can be described as functional diversity (the relative abundance of functionally different kinds of organisms), community diversity (the number sizes and spatial distribution of communities or patchiness), and landscape diversity (the diversity of scales of patchiness) (Pearce et al. 1994). By conserving biodiversity at the ecosystem level, not only can constituent species be preserved, but the ecosystem functions and services can also be protected.

Conservation Biology

Biodiversity is the common wealth of human beings. Biodiversity has very important values,

not only utilitarian value but also intrinsic value. The utilitarian value can be divided into direct utilitarian value (e.g., as food, fuel, and materials), ethical and moral value, ecological value (e.g., soil formation and protection, nutrient storage and cycling), aesthetic value (e.g., Ecotourism), and so on (Mutia 2009). Intrinsic value of biodiversity refers to the value of biodiversity in and for itself, regardless of its utility and usefulness. Biodiversity is disappearing at an unprecedented rate as a result of human activities. The key pressures causing biodiversity loss are overexploitation of biological resources, environmental pollution, climate change, invasive alien species, the degradation, fragmentation, destruction of habitats, and so on (Butchart et al. 2010). With the increasing problems of biodiversity, people recognized that the protection of biodiversity is very necessary. In order to maintain the sustainable development of biodiversity, conservation biology as a crisis discipline was birthed.

In 1978, the First International Conference on Conservation Biology was held at the San Diego Wild Animal Park in the United States. In 1985, the formal organization and incorporation of the Society for Conservation Biology (SCB) was established. At the beginning, Soulé noted that “conservation biology is a crisis discipline grounded in the recognition that humans are causing the death of life – the extinction of species and the disruption of evolution” and its goal was to provide principles and tools for preserving biodiversity (Soulé 1985). Currently, conservation biologists have shifted focus from the problem of “endangered species” to “loss of biodiversity.” The two major missions of conservation biology are to conserve the biodiversity on the Earth and safeguard the benefits that human welfare access through the functional operation of ecosystems (Dyke and Lamb 2020). Conservation biology is a synthetic, eclectic, and multidisciplinary discipline.

Protecting and improving the ecological integrity and long-term viability of the core regions rather than patches should be the basic feature of biodiversity conservation strategies (Ayyam et al. 2019). In-situ and ex-situ conservations are the two basic types of conservation methods. Ex-situ conservation refers to conservation of components of biodiversity in selected areas outside

their natural habitats, including botanical gardens, zoological gardens, and conservation stands (Ayyam et al. 2019). In-situ conservation refers to conservation of species in their natural habitats or natural ecosystems, including national parks, sanctuaries, and biosphere reserves (Ayyam et al. 2019).

Marine Biodiversity

Marine system possesses its own unique array of biodiversity. It must be considered carefully and separately in evaluating their abundant life and resources. Marine systems are disproportionate contributors to the global biodiversity. The estimates number of extant marine species range from ~300,000 to 2.2 million using different assessment methods (Luypaert et al. 2020). Of the estimated marine species, approximately 226,000 eukaryotic marine species have been described as of 2012 (Appeltans et al. 2012), and now, approximately 235,000 have been described (WoRMS Editorial Board 2020). There is considerable uncertainty in estimates of the exact number of marine species and this uncertainty is particularly caused by most of the marine habitats being under-sampled and the biological groups with few taxonomic experts (Luypaert et al. 2020).

Marine biodiversities are vulnerable to human activities and they are under threat when their resources extracted in destructive ways. The threats listed by the IUCN can be grouped into six categories: habitat destruction and modification, over-exploitation, invasive alien species, pollution, climate change, and other (Young et al. 2016; Luypaert et al. 2020). Habitat destruction and over-exploitation are the major cause of declines of marine species. Habitat destruction is “the reduction in habitat quality or complete removal/conversion of ecosystems and their related functions” (Luypaert et al. 2020). Marine habitat can directly effect by human intervention (e.g., bottom trawling, pollution and mining) or indirectly caused by ocean warming, acidification, and so on (Rossi 2013). Overexploitation can not only cause the decline of target species but also affect populations of other non-target species through multiple collateral effects. Almost 80% of the world’s fisheries are overexploited and some of

them are in a state of collapse (Imtiyaz et al. 2011). Overfishing is the greatest threat to the endangered or vulnerable extinction species, and it threatens many other species, particularly large sized fishes (e.g., sharks, swordfish) (Imtiyaz et al. 2011). Marine pollutions, including heavy metals, oil spill, and marine debris, can have important consequences for marine species (Ayyam et al. 2019). An invasive alien species, intentionally or accidentally transported into an environment outside of its historic geographical range, can create and change the original habitat and influence the structure and function of marine ecosystems (Dyke and Lamb 2020). Climate change with rising temperatures and more frequent extreme climate events, causing ocean acidification and expanding marine dead zones, led to wide and varied consequences for marine biodiversity (Ayyam et al. 2019; Dyke and Lamb 2020).

The loss of marine biodiversity is widely acknowledged and it is very important and urgent for the conservation of marine biodiversity. To date, 7.7% of the ocean is protected according to the World Database on Protected Areas (WDPA) and 2.7% of the ocean is fully or highly protected from fishing impacts (Marine Conservation Institute 2021). Marine biodiversity hotspots, a combination localities of high species richness, endemism or threat, are always prioritized sites of conservation (Jefferson and Costello 2019). There are 18 marine biodiversity hotspots globally, including The Coral Triangle, the waters of Japan, and China, the South Africa or the Eastern African region, and so on (Jefferson and Costello 2019). Marine protected areas (MPAs) have shown promising roles on marine biodiversity conservation. Large MPAs may be ideal for biodiversity conservation but may limit the exploitation of fish stocks to well below sustainable levels, and small MPAs may provide a conservation of the sedentary species but unlikely to provide an effective refuge for highly mobile species (Luypaert et al. 2020). According to the experience of already known MPAs, successful MPAs often have the key features of being no-take zones, well-enforced, older than 10 years, larger than 100 km², and isolated by deep water or sand (Edgar et al. 2014).

Important International Conventions/Plans

Convention on Biological Diversity

The Convention on Biological Diversity (CBD) is a legal international treaty for biodiversity conservation. CBD was first signed at the United Nations Conference on Environment and Development in Rio de Janeiro in June 1992 and came into force in 1993. Over 150 governments signed the document at the 1992 Rio Earth Summit, and since then more than 175 countries have ratified the agreement. CBD is dedicated to promoting sustainable development and established with three main goals: conserve biological diversity, use its components sustainably, and share the benefits from the use of genetic resources fairly and equitably (Convention on Biological Diversity 2000). To advance these goals, the signatories pledged to develop plans to “protect habitats and species; provide funds and technology to assist developing countries to provide protection; ensure commercial access to biological resources for development; share revenues fairly among sources and developers; establish safety regulations and accept liability for risks associated with biotechnology development” (Parson et al. 1992). In order to make the conventions properly implemented, the Conference of the Parties (COP), composed of governments that have ratified the convention, take periodic meetings to check the progress of the convention, identify new protection priorities for member states and develop work plans (Cooper and Mooney 2013). The Global Environment Facility (GEF) projects, providing financial mechanisms, help forge international cooperation and finance actions to address critical threats to the global environment.

The Census of Marine Life

The Census of Marine Life (CoML) is the largest, broadest, and most invested international cooperative of marine life surveys by far. The program lasted from 2000 to 2010, involving more than 2700 marine biologists from more than 80 countries and setting out more than 540 voyages (Ausubel et al. 2010). The voyages involved the survey of marine biodiversity at almost all depths, environments and ocean areas of the world, especially in the deep sea, hot springs, seamounts, cold springs,

and other marine environments. The study collated a large amount of historical data, evaluated the diversity of species and the distribution of marine life, and established a research system for marine biodiversity. The research content of CoML mainly includes the following aspects: History of Marine Animal Populations (HMAP), Future of Marine Animal Populations (FMAP), and the Ocean Biogeographic Information System (OBIS) (O’Dor and Yarincik 2003). The Census made tremendous achievements, many books, papers, websites, videos, films, maps, and databases were published or established. It increased the estimate of known marine species from about 230,000 to nearly 250,000, found more than 6000 potentially new species, and completed formal descriptions of more than 1200 of them (Ausubel et al. 2010). The Census found life everywhere even in unexpected places at the site of a hydrothermal vent in the deep Mediterranean where the first discovery of anaerobic animals living without oxygen (Ausubel et al. 2010). However, the study also found that overfishing, habitat destruction, alien species, pollution, rising sea temperatures, and ocean acidification are threatening the survival of marine life, and the populations of some marine organisms are gradually shrinking or even on the verge of extinction.

Key Applications

Biodiversity and Ecosystem Services

Biodiversity can provide human beings economic values through its use values and non-use values (Pearce et al. 1994). It plays an important role in providing ecosystem services and the demand of people from those services. Ecosystem services are “the benefits people obtain from ecosystems. These include provisioning services such as food and water; regulating services such as regulation of floods, drought, land degradation, and disease; supporting services such as soil formation and nutrient cycling; and cultural services such as recreational, spiritual, religious, and other non-material benefits” (Millennium Ecosystem Assessment 2005). The loss of biodiversity

caused by intensified human activities has led to serious degradation of ecosystem services and conservation efforts have only recently begun to recognize the role of biodiversity in ecosystem services. Scientists and government have made some efforts from biodiversity and ecosystem level approaches, such as ecosystem-based management (EBM) and the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES). EBM is “a management approach that defines management strategies for entire ecosystems, not simply individual components of ecosystems and it takes into account interactions among ecosystem components and management sectors” (Dyke and Lamb 2020). The IPBES was established in Panama City in 2012 to “strengthen the science policy interface for biodiversity and ecosystem services for the conservation and sustainable use of biodiversity, long term human well-being and sustainable development” (<https://www.ipbes.net/>).

Deep-Sea Marine Biodiversity

Deep-sea is the largest reservoir of ecosystems and biodiversity on the planet. It contains a variety of complex environments, such as plains, seamounts, trenches, abysses, hydrothermal vents, and cold seeps, giving birth to unique ecosystems and life processes. The World Register of Deep-Sea Species database has recorded 25,902 species

at depths of more than 500 m, including plankton and benthos, as well as many microorganisms (Glover et al. 2020). The richest biodiversity areas involved in hydrothermal vents, cold seeps, and seamounts in deep-sea.

Hydrothermal vents are fissures on the seafloor from which geothermally heated water issues (Fig. 1). They are usually found near deep-sea areas with active crustal movements, such as mid-ocean ridges, back-arc basins, and intracontinental rift valleys. There are many large invertebrates congregated on there and formed oases of life in the deep-sea. In 1977, the first hydrothermal vent was discovered at the depth of 2500 m of the Galapagos in the East Pacific Rise mid-oceanic ridge using the manned submersible “Alvin” (Gallardo 1977). Varieties of macrobenthos, such as tubular worms, shellfish, and crustaceans, thrive around hydrothermal vents by grazed, filtered, or hosted with these microorganisms. Chemosynthetic microbes are the primary producers in the vent food web, and they can provide nutrition for the vent animals. By 2011, the Biogeography of Chemosynthetic Ecosystems (ChEss) databases listed more than 700 hydrothermal vent species (German et al. 2011). Among them, arthropods, molluscs, and polychaetes are the most abundant taxa and account for more than 90% of all hydrothermal biological species (Tunnicliffe and Fowler 1996).

Biodiversity

Conservation, Fig. 1 A chemosynthetic community with caridean shrimp as a dominant species found around a chimney of hydrothermal vent from the Okinawa Trough at about 970 m depth. (Photographed by ROV “Faxian” of the Institute of Oceanology, Chinese Academy of Sciences, provided by Dr. Xin Zhang)

Cold seeps are areas of the seafloor where hydrocarbon-rich fluid seepage occurs and gases leak from fissures and emerge through the sediments and into the water column, which support a characteristic biome based on chemosynthetic organisms (Dong et al. 2020) (Fig. 2). The first cold seep was discovered on the Florida Escarpment in the Gulf of Mexico at a depth of 3200 m (Paull et al. 1984). By 2011, some 600 cold seep species have been described and listed in the ChEss database (German et al. 2011). The density of macroinvertebrates in cold seeps is significantly higher than that in the surrounding seafloor environment, but the species diversity is lower (Oliver et al. 2011). The species of ecosystems are similar within seep and vent habitats in the composition at the high taxon level, but there are significant differences at the species level (Sibuet and Olu 1998). The epibenthic macroinvertebrates always have low diversity and high dominance of single species, especially the molluscan and polychaete species (Oliver et al. 2011).

Seamounts are widely distributed topography with summit depths at least 100 m above the seafloor, which are often formed by volcanic activity (Yesson et al. 2011). Seamounts may be divided into hills (<500 m from seafloor), knolls (>500 m from seafloor), and seamounts (>1000 m from seafloor) (Yesson et al. 2011). There are more than 150,000 seamounts and

knolls and more than 25 million seamounts with summit depths at least 100 m (Wessel et al. 2010; Yesson et al. 2011). Seamounts are hotspots of pelagic biodiversity in the ocean. The biomass, abundance, and diversity of plankton, swimming organisms, and benthos of seamounts are often higher than those of other deep-sea ecosystems (Rogers 2018). Suspension feeders (e.g., sponges, corals) usually dominate the communities of the megabenthos on seamounts, and they can provide important habitat for mobile invertebrates such as molluscs, crustaceans, and echinoderms (Rogers et al. 2008). Some fish can form aggregations around seamounts and pelagic marine predators (e.g., shark, tuna) are attracted to improve opportunities for foraging. Very few data of invertebrates living at seamount are available and over 100,000 seamounts were estimated worldwide, only 200 of seamounts have been biologically sampled (Samadi et al. 2008). The reported number of seamount species may be seriously underestimated of the total number due to very few surveys have confirmed the complete specimens collected into an accurate species as the lacking of taxonomical expertise globally (Samadi et al. 2008). The limited habitat, apparently limited recruitment between seamounts, extreme longevity, and highly localized distribution of many species make seamount communities highly vulnerable to the impacts of fishing

Biodiversity

Conservation, Fig. 2 A chemosynthetic community (*Bathymodiolus platifrons*–*Shinkaia crosnieri* community) found in Jiaolong Cold Seep I at about 1120 m depth in northeastern South China Sea (Li 2017)

(Samadi et al. 2008). Temporary fishing closures and the establishment and enforcement of permanent protection zones are required to achieve efficient and long-term protection of seamounts (Samadi et al. 2008).

Definition

Block assembly is a technological process of sub-assemblies and parts into ship block, also known as block manufacturing. According to the characteristics of block production, it can be divided into flat section, curved section, and superstructure section. According to statistics, in modern shipbuilding, hull assembly and welding account for 12–18% of the total labor in shipyard construction. Therefore, improving the mechanization and automation level of assembly and welding work can not only reduce the labor intensity of workers but also effectively shorten the shipbuilding cycle and improve the product quality. Due to the adoption of new technologies such as digital amplification and numerical control, the accuracy of parts processing is continuously improved and the

mechanization of assembly work is implemented (Liu and Wang 2011).

Introduction

Subassembly Line

There are usually four types of subassemblies: composite members of T iron, internal members of flat section, internal members of curved section, and iron outfits. Foreign large and medium-sized shipyards generally use T iron production lines (some of which are automatic production lines), equipped with automatic transfer rollers, gantry type cutting machines, robot welding machines, and corresponding sorting devices, which have higher production efficiency. Some steel mills roll different specifications of T iron for shipyards, and even there are specialized factories that specially assemble various T iron.

For the subassemblies of the flat and curved sections, several technological processes are generally adopted as followed: parts positioning, assembly welding, turning, and assembly. According to the size of the batch, manual welding is generally used on the platform, or mechanized installation and welding equipment is adopted with the auxiliary of transfer roller. In the case of mass production, mechanized frame production lines can be set up or the production lines can be formed as part of a certain sectional production line. For some iron outfits, they are generally assembled on the platform in the specified area of the hull workshop (Xu 2005).

For some large batches of splicing plates, reinforced webs and flat grillages, welding stations with higher degree of automation, such as pressure frame splicing plates and reinforced webs with high efficiency, can be used as part of the flat sectional assembly line. For many skeleton frameworks and frames in ship construction, shipyards generally adopt special and efficient welding assembly stations. For example, when Hudong Shipyard was building 70,000 DWT grade bulk carrier, it considered that there were 180 frames in the bottom section, so it adopted a special station and a flow line operation method. Its production process was as follows: steel plate pretreatment, numerical control cutting, partial assembly welding, distortion

correction by frame, frame welding and hoisting into the outfield for block manufacturing. In this way, the speed of block construction is greatly improved (Liu and Wang 2011).

Block Assembly Line

The structure and shape of the hull are complex and diverse, and it is unrealistic to use a mechanical device (or an assembly line) to complete the manufacture of all blocks. Therefore, when studying the construction of hull block assembly line, it is necessary to divide the sections into several types according to the similarity of the structure and appearance characteristics of various blocks, and formulate standard process regulations according to the section types, so as to form various mechanized intelligent production lines. Flat section and curved section are two basic sections in hull section, and their structures are typical, accounting for a considerable proportion of the workload, of which flat section has more workload. Therefore, at present, the research and test work of mechanized, automatic, and intelligent production lines are all carried out with these two sections as the objects (Ryu et al. 2020).

Flat Section Line

Generally speaking, the percentage of flat section must be at least 20%, and the establishment of flat section line is of practical value (Li and Wei 2006). With the large scale of ships, shipbuilding industry attaches great importance to block manufacturing, especially flat sectional manufacturing. Major shipyards generally adopt flat section assembly lines, and the technical level and production efficiency are continuously improving.

1. Coverage of Flat Section Assembly Line Process

Under normal circumstances, the flat section assembly line can include: waiting station (plate, longitudinal, floor, preoutfitting item), splicing plate assembly station, splicing plate welding station, inspection and repair station, marking and cutting transposition, longitudinal assembly station, longitudinal welding station, transverse movement station, floor assembly station, floor welding station, turning station, preoutfitting station, and delivery station.

The number of work stations in the assembly lines varies from factory to factory. According to the specific situation, there are usually 8–10 work stations. The main work station consists of steel material preparation, panel tailor-welding, marking and cutting, skeleton framework assembly welding, and transportation. The transportation of blocks between stations usually adopts transfer roller.

2. Typical Process Flow of Flat Section Production Line

Flat section is a unit structure formed by welding two or more than two steel plates into a panel, and then welding with various skeleton frameworks such as longitudinal trusses and frames. It is mainly composed of flat panel and flat frame. Therefore, its manufacture can be divided into two parts: tailor-welded panel and welding frame. According to the welding methods adopted, the automatic welding of the flat panel can be divided into double-side automatic submerged arc welding and one-side submerged arc welding with flux copper backing (FCB). In the former, the panel turning station should be added to the splicing plate assembly line so as to carry out panel turning and back sealing welding. The latter can save the plate turning station. Typical process of plane sectional production line includes: the whole line assembly and welding method (Fig. 1) and the frame assembly and welding method (Fig. 2).

In the whole line assembly and welding method, one component or a group of components is positioned one by one, installed and welded to the strake, and another component is installed and welded after the one component is installed and welded to form a flat section.

The frame assembly and welding method is to assemble and weld the longitudinal and transverse components into box frame of well shape, and then assemble and weld it to the strake.

At present, large shipyards in our country generally have flat section assembly lines. Most shipyards have introduced advanced flat section assembly lines from abroad, and some shipyards have built their own flat section production lines (Huang 2013).

Block Erection Technology

Yujun Liu
School of Naval Architecture and Ocean Engineering, Dalian University of Technology, Dalian, China

Definition

Block erection, also known as ship assembly, is the technological stage of completing the overall assembly, welding, outfitting, and painting of the ship on the shipbuilding berth (dock) on the basis of pieces assembly and welding, block and block assembly and welding, pre-outfitting, and pre-

painting. Ship assembly is commonly known as ship general closure. As ship assembly generally needs to be carried out in the berth or the dock which are very limited and important resources of the shipyards, the quality and speed of ship assembly have a great impact on ensuring the quality of ship construction and shortening the period of ship construction (Liu et al. 2011).

Introduction

Ship Assembly Facilities for Ships: Berth and Dock

The shipbuilding berth (dock) is the working place where the block is assembled into the whole hull. It should have a solid foundation and be generally set up near the hull assembly and welding workshop and close to the launching water area of the ship, so as to shorten the transportation route of the block and facilitate the ship launching.

Shipbuilding Berth

The shipbuilding berth is a place where ships are built on land. It can be moved to the water area by launching device. Generally, it can be divided into inclined berth, horizontal berth, and semi-dock berth. The shipbuilding berth also includes a longitudinal inclined berth and a transverse inclined berth, which determine the direction of the ship's gravity launching.

The inclined berth plane and the horizontal plane have a certain inclination (called berth slope), which is generally taken as $1/14 \sim 1/24$.

Taking the longitudinal inclined berth as an example, the foundation of the longitudinally inclined berth is composed of reinforced concrete (Xu 2011). Parallel crane tracks are laid along both sides of the berth, and cranes with large lifting capacity are equipped. According to the inclination angle of the berth and the requirements of ship closure, the lifting height is required to be higher. The advantage of this kind of berth is that the ship is built and launched at the same position, and the construction site is relatively compact. Generally, there is no need to move the ship. The ship can slide into the water under the action of its own gravity, so there is no need for a special ship moving device. Inclined berth is usually used in combination with oiling and steel ball slideway, which is the most widely used at present (Fig. 1).

The Dock

A dock is a hydraulic structure that is lower than the horizontal level and has a gate at its end. After the gate is closed, the water can be drained to be used for shipbuilding. It has some advantages of horizontal berth, and the ship is also built in a horizontal state (Li et al. 2006). Moreover, the dock bottom of the building ship is lower than the ground level, the lifting height of the block is reduced, and gantry cranes with large span and large lifting mass can be configured across the dock and the pre-installed welding area on the dock side, which greatly improves the mechanization degree of ship construction. Dock launching can greatly simplify the process of ship launching and is suitable for building large

ships. In addition, the dock is not only used for shipbuilding but also convenient for ship repair. However, the investment in the dock is large, and the scale of ships built in the dock is strictly limited (Fig. 2).

General Assembly Method of Ship

Due to the different product objects and shipyard production conditions, the ship assembly methods (called construction methods) are also various. These methods are all determined according to the structural characteristics of the ship and the production conditions of the shipyard and are conducive to balancing the production load, improving the efficiency, shortening the shipbuilding cycle, and improving the working conditions.

The most commonly used methods are the block method of hull construction, tower method of hull construction, island method of hull construction, and series method of hull construction (Tokola et al. 2013).

Block Method of Hull Construction

The construction method of taking block as the hull assembly unit can reduce the berth workload and welding deformation, improve the integrity of pre-outfitting and pre-painting operations, move the workload forward, and shorten the berth construction period due to the large size, good rigidity, and relatively complete space. However, the size and weight of the block are generally limited

Block Erection Technology, Fig. 1 Shipbuilding berth

Block Erection Technology, Fig. 2 The dock

Block Erection Technology, Fig. 3 Block method of hull construction

by the lifting capacity of the berth. In the block method of hull construction, the block in the middle of the ship (or close to the middle of the ship) is hoisted to the berth for positioning and fixing, and then the adjacent blocks before and after are hoisted in turn. When the butt joint welding of the two blocks is completed, the outfitting work can be carried out (Fig. 3).

Island Method of Hull Construction

The method of hull construction has only one construction area, the berth area cannot be fully utilized at the initial stage of assembly, the berth building period is long, and the stem and stern of the completed ship are tilted greatly. Therefore, if the hull is divided into 2–3 construction areas (hereinafter referred to as “islands”), each island selects a benchmark block and is constructed simultaneously according to the tower method of hull construction. The islands are connected with each other by embedded blocks, which can make full use of the berth area, expand the construction surface, and shorten the berth building period. Moreover, the length of its construction area is shorter than that of the tower method of hull construction and the hull rigidity is larger, so its

total welding deformation is smaller than that of the tower method of hull construction. This construction method is called the island method of hull construction. The hull is divided into two construction areas, which is called the two-island method of hull construction. The method of dividing into three construction areas is called the three-island method of hull construction. However, the assembly and positioning operation of its embedded blocks are relatively complicated. As shown in Fig. 4, it is a two-island method of hull construction, in which the blocks are embedded and complementary blocks (Bao et al. 2009).

Series Method of Hull Construction

When some shipyards use larger berths to build ships with smaller tonnage ships, they often use the series method of hull construction to organize production and improve the utilization rate of the berths. The series method of hull construction is to build the stern of the second ship at the stem of the berth (dock), while the first ship is built at the stern of the berth (dock). After the first ship is launched, the stern of the second ship is moved to the stern of the berth (dock), and other blocks are continuously hoisted to form the whole hull. At the same time, the stern of the third ship is built at the stem of the berth, and so on.

This form can greatly improve the utilization rate of berths, shorten the construction period of berths (docks), and carry out outfitting operations in advance. It has many advantages in improving production management and balancing

Block Erection Technology, Fig. 4 Two-island method of hull construction

Block Erection Technology, Fig. 5 Series method of hull construction

production rhythm. However, it can only be used when the length of the berth is greater than the length of the building ship (approximately 1.5 times the length of the ship), and when this method is used on the inclined berth, ship moving equipment must also be equipped. Similarly, if a large dock is used to build a small tonnage ship, and if the dock can accommodate more than one ship, many ships will be built simultaneously in the dock. When a ship needs to be launched after the final assembly, the dock door shall be opened for water inflow. Other ships that have not been completed shall be limited in position by ballast and other technical means. The launched ships shall float upward by buoyancy and be towed outside the dock. After the dock door is closed and the water is drained, other ships shall continue to be built. In actual production, there are also various construction methods. At present, on the basis of vigorously promoting pre-outfitting shipbuilding, the domestic shipbuilding method is changing toward the modern shipbuilding mode, which is guided by the theory of overall planning and optimization, applies the principle of group technology, takes intermediate products as the guidance, organizes production according to

regions, separates the hull, outfitting and painting operations in space and orders in time, realizes the integration of design, production, and management, and realizes the balanced and continuous assembly shipbuilding (Kim et al. 2012). It is worth mentioning that no matter what kind of modern shipbuilding mode, in the shipbuilding process, it is based on several common methods of sectional construction that have been described, and optimizes the combination in time and space respectively, so as to achieve the purposes of expanding the production scale, improving the production efficiency and reducing the manufacturing cost (Fig. 5).

Tower Method of Hull Construction

During construction, the bottom block at the back of the middle part is taken as the reference block (for medium-sized ships, the engine room block can also be taken). The reference block is positioned and fixed on the berth, and then each block is hoisted from bottom to top to the stern and stern and both sides. Since the installation area formed during the construction process is in the shape of a pagoda with wide bottom and narrow top, it is called the tower method of hull construction, as

Block Erection Technology,

Fig. 6 Tower method of hull construction

B

shown in Fig. 6. The sectional installation of this construction method is relatively simple, but the berth building period is relatively long, and due to the large number of welded closing joints, the welding deformation is not easy to control, and the stern and stem of the ship are seriously tilted after completion.

General Assembly Technology of the Berth (Dock)

Tower method of hull construction and island method of hull construction are commonly used for ship assembly. Although the construction methods are different, the sequence of sectional hoisting and the fixing method of sectional positioning in a construction area are the same. At the same time, through the discussion and analysis of the block assembly technology, the block assembly technology of the block construction method can also be obtained. Therefore, taking the tower method of hull construction as an example, the relevant issues of berth assembly and welding sequence and welding process of berth assembly are discussed.

Sequence of Berth Assembly and Berth Welding

In general, the sequence of berth assembly and berth welding for the tower method of hull construction is as follows:

1. Hoisting reference block.

The hoisting reference block is the starting point for berth closure, and its selection should enable berth outfitting and hull construction to be completed at the same time. Due to the heavy outfitting workload of the engine room, the starting point is often selected in and

around the engine room, so as to complete the hull of the engine room as soon as possible and carry out outfitting operations as soon as possible.

2. Bulkhead block and front and rear bottom block on the hoisting reference block.
3. Hoist broadside block. Continue to hoist the bottom block and bulkhead block in the stern and the stem directions.
4. Hoist the deck block. Continue to hoist the bottom block, bulkhead block, and broadside block, and sectional seam welding is carried out at the part where the mega-block of the ship hull has been formed.
5. Continue to hoist the bottom block, bulkhead block, broadside block, and deck block in the stern and stem directions, weld the assembled block large joints, and carry out outfitting operation on the cabins where the block large joints have been welded.
6. Hoist the stern and stem block, and continue to complete the welding of large seams in blocks and outfitting in the cabin.
7. Hoist and weld superstructure, and continue outfitting operation.

When the island method of hull construction is adopted, the assembly and welding sequence of each construction area are the same as that of the tower method of hull construction, except that the work of hoisting, embedding, and repairing blocks is added at the end to connect each construction area. In actual production, sometimes due to the influence of sectional supply, reasonable utilization of hoisting equipment, and other temporary factors, it is required to adjust the sequence of hoisting in certain blocks. In this regard, it is necessary to proceed from reality. As long as it does not cause difficulties in berth assembly and welding, appropriate adjustments can be allowed (Huang 2013).

Ship Berth Assembly and Welding Technology

Sectional positioning, allowance drawing and cutting, large joint fixing requirements, and large joint welding are common technical problems in berth assembly and welding, which are discussed and analyzed respectively.

Positioning of Blocks on the Berth

1. Primary Positioning.

The correct position of the blocks in the hull is determined directly by the four factors of the length, width, height direction, and horizontal inspection line of the blocks in the hull. Take the positioning of double bottom blocks as an example, the frame inspection lines on the blocks are aligned with the corresponding frame lines on the berth to determine the position of the blocks along the length direction; align the block centerline with the berth channel centerline to determine the position in the width direction; determine the position of the sectional height direction based on the height benchmark; measure the block left-right level inspection line to determine the block left-right level. After the positioning is completed, the blocks will be fixed.

2. Secondary Positioning.

If the blocks are assembled on the berth with the allowance, a secondary positioning is often required. Take the bulwark block with allowance on the berth as an example. First of all, the blocks are hoisted onto the berth. And align the horizontal inspection line of the block with the same horizontal inspection line on the previous side block that has been assembled. Draw the allowance line in the height direction, remove the broadside block and cut off the allowance, then hoist the block onto the berth, align the frame inspection line of the block with the same frame inspection line on the bottom block, draw the allowance line in the length direction, and remove and cut off the allowance. At last, hoist the block onto the berth, complete the block according to the frame inspection line and the horizontal inspection line, and finally complete the secondary positioning.

Determine the Allowance, Draw the Allowance Line, and Cut the Allowance

In the shipyards where precision control is implemented, the assembly is carried out on the berth without any allowance in blocks. The allowance of the large joints in blocks is cut off on the sectional mold bed and then hoisted on the berth. This can cancel the operations of drawing lines, cutting and secondary positioning of the block, reduce the amount and difficulty of berth assembly operations, and shorten the assembly period of the berth. However, due to the limitation of technical conditions, some shipyards have not yet implemented the precision control of berth assembly, so the sectional large joints need to have an allowance, and the allowance drawing and cutting will be carried out when the ship is closed.

Sectional Drawing, Butt and Positioning Welding

After cutting the block allowance, the groove shall be correctly processed, then the block shall be drawn in, and the block installation position and joint clearance shall be checked. After meeting the requirements of positioning welding, the block positioning welding shall be carried out, and the internal framework near the large joint shall be installed. First, the internal framework of the block is positioned and welded, and then the external plate is positioned and welded.

In the method of sectional drawing and matching, the bottom block and the block are generally supported by a hydraulic jack and are drawn and positioned by elastic screw buckle (also known as flower basket screw). The other blocks are drawn and matched with elastic spiral buckles.

When positioning welding is carried out for sectional joints, the phenomenon that two frameworks are not aligned often occurs. At this time, the positioning welding between one framework and the plate can be removed by about one gear frame distance, or the positioning welding between the two butted frameworks and the plate can be removed to make them straight or aligned (Fig. 7).

Block Erection Technology, Fig. 7 Cutting the block allowance

Welding Work in Berth Assembly

In order to prevent welding deformation, a strong back should be added after positioning welding of the outer plate, and welding should be carried out symmetrically left and right. Before welding, several blocks should be assembled to increase the rigidity of the hull and make it difficult to generate welding deformation. During welding, the inner surface shall be welded first, and the outer back sealing shall be welded.

The welding operation of sectional large joints is carried out in parallel with the sectional hoisting operation. This is not only conducive to reasonably organizing the production process of berth assembly and welding but also can reduce the warping deformation of the hull when the length of the construction area is short.

In order to reduce the total welding deformation of the hull, the welding operation should be carried out in the area where the mega-block has been formed, so that it has strong structural rigidity of the hull and is convenient to meet the requirements of symmetrical welding.

In recent years, with the continuous improvement of shipbuilding equipment automation, some shipyards have begun to use vertical welding robots in the welding of large hull joints, greatly improving the speed and quality of berth closure seam welding.

Conception of Bucket Foundations

The world's escalating demands for energy, combined with the continued depletion of oil and gas reserves in shallow waters, has resulted in offshore developments moving into deeper waters and untested environments. In the Gulf of Mexico, West Africa, offshore Brazil, and, more recently, off Australia, developments have proceeded into water depths in excess of 1000 m. These deep

water developments usually consist of moored floating facilities, which are tethered to the seabed via an anchoring system.

Bucket foundations (also named as suction caissons or skirted foundation) have been proven as a cost-effective alternative to more traditional anchoring solutions such as piles and drag anchors, because of their ability to confine surface soil and transfer loads to stronger soils at skirt tip level. Bucket foundations are a type of shore shallow foundations, which consist of a plate resting on the seabed and a peripheral skirt (often supplemented by internal skirts) penetrating into the seabed and confining a soil plug. Bucket foundations are best described as upturned foundations that are installed into foundations to anchor floating structures or to support superstructures. The skirts also assist in foundation installation by constraining the lateral movement as the foundation approaches the seabed, compensating for seabed irregularities and reducing scour around the foundation periphery. Bucket foundations (also called buckets, skirted foundations, or suction anchor piles) can be used to sustain high axial and lateral loads. These foundations may be broadly divided into two types; relatively short buckets, often referred to as bucket foundations, which support jacket structures, and relatively long buckets, which are used as foundations for moored structures, which typically have higher aspect ratio than bucket foundations. The typical shapes of bucket foundations are circular and square. For square buckets, the width of edges usually ranges from 3 m to 10 m (Hossain et al. 2012). For buckets with circular shape, it comprise large diameter cylinders, typically in the range of 3–8 m (shown in Fig. 1), open at the bottom and closed at the top, and generally with a length to diameter ratio L/D in the range three to six, considerably less than offshore piles, which have slenderness ratios up to 60. Bucket foundations are a comparatively new foundation system, which have however found relatively widespread use. Bucket foundations have proven to be a cost-effective, excellent performing, deep foundation system, that is utilized in offshore engineering worldwide. Typically, they are used for bridges, offshore wind power, cofferdam, and large structures, where large loads and lateral resistance are

major factors. The first bucket foundation employing the system as permanent foundations in clay or sand were built in the early 1990s (Tjelta et al. 1990).

The foundation keeps water out of the construction area while its open bottom allows workers to place foundations and piers in the seabed or riverbed. In shallow water, an open bucket is used; its open top allows light and air to enter from above the water line. For deep-water construction, a pneumatic bucket has a closed top; pressurized air is pumped in, and personnel enter and leave through an airlock. Either type has a sharply inclined lower edge, allowing the structure to be deeply embedded in the ground so water cannot seep in.

A bucket must be firmly mounted on a stable foundation for maximum security and efficiency.

Bucket Foundations, Fig. 1 Bucket foundation used in offshore engineering. (After Dendani and Colliat 2002)

Engineers prefer to choose a layer of stiff soil to construct on it. If bedrock is too far beneath the ground, they will sometimes rely on impacted mud or earth, or create an artificial foundation.

Bucket foundations are similar in form to pile foundations, but are installed using a different method. It is used when soil of adequate bearing strength is found below surface layers of weak materials such as fill or peat. It is a form of deep foundation, which are constructed above ground level, then sunk to the required level by excavating or dredging material from within the foundation.

Functions of Bucket Foundation

The application of bucket foundation and loading condition in various offshore structure are shown in Fig. 2, which includes (a) & (b) gravity-based structures; (c) jacket/template structure; (d) tension leg platform; (e) storage tank

Support Vertical Loads

Bucket foundations have proven to be competitive alternatives to more traditional foundation solutions like piles in various types of soils and for a wide range of fixed offshore platforms. Bucket foundations have been used for gravity platform jackets, jack-ups, subsea systems, and seabed protection structures.

Even more critical than settlement is differential settlement. This occurs when parts of the offshore structures settle at different rates,

Bucket Foundations, Fig. 2 Application of bucket foundations and loading conditions in various offshore structures. (After Acosta-Martinez 2010)

resulting in cracks, some of which may affect the structural integrity of the offshore structure.

Support Horizontal Loads

Bucket foundations are used to anchor floating production vessels using catenary or taut wire mooring chains; in these cases, the foundation is under quasi-horizontal or angled load. In shallow water, a length of the bucket foundation chain will rest on the seabed during calm conditions, with the small mooring loads being resisted by friction against the seabed. The chain may be connected to the foundation at the soil surface, or it may be connected via an embedded pay-eye, which provides a more efficient arrangement.

Types of Bucket Foundations

Box Bucket Foundation

Box bucket foundations are watertight boxes that are constructed of heavy timbers and open at the top. They are generally floated to the appropriate location and then sunk into place with a masonry pier within it.

Excavated Bucket Foundation

Excavated bucket foundations are, just as the name suggests, foundations that are placed within an excavated site. These are usually cylindrical in shape and then back filled with concrete.

Floating Bucket Foundation

Floating bucket foundations are also known as floating docks and are prefabricated boxes that have cylindrical cavities.

Open Bucket Foundation

Open bucket foundations are small cofferdams that are placed and then pumped dry and filled with concrete. These are generally used in the formation of a pier.

Pneumatic Bucket Foundation

Pneumatic bucket foundations are large watertight boxes or cylinders that are mainly used for under water construction.

Mechanical Principle of Bucket Foundation

Application of Bucket Foundation

Foundation for Offshore Wind Turbines

Bucket foundations have been widely used in offshore wind turbines in recent decades. The foundation of a wind turbine must be strong enough to withstand the maximum force acting on it and not fail during its operation. Furthermore, it must be stiff enough so that the displacements and rotations during its lifespan fall within the serviceability design criteria of the wind turbine manufactures. Bucket foundations, with high vertical and horizontal bearing capacities, have been used as the foundation for offshore wind turbines (Ibsen and Brincker 2004). A foundation concept that is gaining acceptance for the support of bottom-fixed offshore wind turbines is the suction bucket foundation. This may support the turbine superstructure either as an individual bucket foundation or as a group of three or four bucket foundations below a jacket substructure, as shown in Fig. 3

Bucket Foundations Construction Process

Suction

A suction bucket foundation is installed pumping the water inside of the foundation to install it by the differential pressure inside and outside as shown in Fig. 4. Initially, bucket foundation was installed to a certain depth by the weight of itself. And then, penetration into the seabed is achieved by suction, via a pump connected to a valve in the top cap of the foundation. Water is pumped out from inside the foundation causing the pressure inside the foundation to fall below that outside. This causes a net downward pressure on the top of the foundation forcing it into the seabed.

Jacking

Offshore developments moving beyond the immediate continental shelf into deeper waters (now approaching 3000 m depths) has been driven by the vibrant oil and gas industry and the world's ever-increasing demands for energy.

Bucket Foundations,

Fig. 3 Offshore wind turbine with jacket substructure supported by suction bucket foundations.
(After Bienen et al. 2018)

B

These deep water developments rely on floating facilities (e.g., floating production storage and offloading vessels, tension leg platforms, SPAR platforms, and emerging concepts such as floating liquefied natural gas (FLNG) facilities) moored to the seabed through mooring chains and anchoring systems, with suction bucket foundations being identified as the most viable option. Bucket foundations are also used as foundations to support pipeline manifolds and end terminations, subsea structures, and riser towers. In the renewable energy industry, they are increasingly being considered for anchoring floating turbines.

Suction bucket foundations are installed by pumping water from inside the foundation after it is allowed to penetrate under its self-weight.

Analyses are sometimes carried out using jacking installation process to simplify the problem, especially for bucket foundations in clay, where a foundation is pushed in soil up to the full penetration depth (similar to driven pile).

To comply with the increasing size of the floating facilities to be anchored (e.g., the Prelude FLNG is 488 m long and 75 m wide), suction bucket foundations are designed as longer and wider – currently up to 30 m long, with a length to diameter (aspect) ratio L/D in the range 2–7 (Andersen et al. 2005). As the thickness of the skirt (t) is restricted to less than 50 mm to ensure installation viability, the longer bucket foundations are required to include horizontal ring stiffeners at intervals along the inner wall of the thin skirt with local thickening of the wall in the

Bucket Foundations,

Fig. 4 Bucket foundation installation by suction pressure. (After Andersen and Jostad 1999)

vicinity of the padeye, with or without transverse struts, for structural integrity.

Suction bucket foundations are thin-walled (thickness, $t \leq 50$ mm) and thus prone to buckling during installation or distortion under the horizontal or moment loading. In order to deal with the buckling problems, horizontal ring stiffeners at intervals along the inner wall of the thin skirt are employed with local thickening of the wall in the vicinity of the padeye, with or without transverse struts. As such, horizontal ring stiffeners at intervals along the inner side of the thin skirt, and occasionally vertical stiffeners around the internal periphery, are employed with local thickening of the wall in the vicinity of the padeye, with or without transverse struts, as shown in Fig. 5. Recent designs of rectangular steel foundations for skirted gravity-based platforms have required combined vertical and horizontal stiffening (after Watson and Humpheson 2007). Consequently, Engineers are faced with the challenge of designing foundations with sufficient structural integrity to allow longer skirt lengths while ensuring their installation feasibility. These stiffeners may increase the required installation pressure by as

much as 50–100% and can have a significant influence on the drained tension capacity (House and Randolph 2001; Westgate et al. 2009).

The addition of these stiffeners has created significant uncertainties regarding the soil flow mechanisms, in particular the inner soil heave with the risk of potential penetration refusal prior to reaching the designed installation depth (or achieving the designed capacity to sustain operational loadings). The pattern of soil flow at the foundation tip, and the proportion of the bucket foundation wall that is accommodated by inward or outward displacement of the soil, has important consequences for quantifying (i) the external radial stress and excess pore pressure, and ultimately long-term external shaft friction following consolidation; (ii) the internal side friction and stiffener end bearing. The behavior of the clay plug can also affect the maximum penetration depth of the foundation. This is more critical for stiffened bucket foundation. If the plug remains fully or partially self-supporting above the horizontal stiffeners, the gaps formed between the stiffeners result in greater heave volume, and hence higher inner seabed elevation. This entry

Bucket Foundations,

Fig. 5 Bucket foundation with stiffeners. (After Westgate et al. 2009)

B

has specifically focused on the quantification of inner soil heave during installation of stiffened bucket foundations.

Andersen et al. (2005) discussed predictions for four different hypothetical installation cases and six case histories carried out by four predictors using their normal design method. For the hypothetical cases, the predictors calculated different soil heave height inside bucket foundation due to different assumptions in terms of the proportion of soil flow inside bucket foundation, soil plug heave standing ability, and soil infilling in the gaps between the embedded stiffeners. For the case histories presented, comparison between the calculated and observed soil heave showed that soil infilling in the gaps between the embedded stiffeners dictated the soil heave height, with the assumption of no soil infilling in the gaps and fully filled gaps providing over and under predictions, respectively.

The stiffeners have a significant effect on the soil flow mechanism of stiffened bucket foundation installation (Zhou et al. 2016). They found that the soft soil will be trapped between stiffeners and move vertically with the same velocity as foundation installation, and the stiffeners have effect on the soil movement around skirt tip and stiffeners. Consequently, it also has effect on the inside heave as reported by Zhao et al. 2017.

Advantages and Disadvantages of Bucket Foundation

Advantages of Bucket Foundations

- Economics
- Reduced weight
- Increased installation speeds
- Ease of decommissioning

- Suitable for deep waters and large turbines
- Slightly less noise and reduced vibrations
- Easily adaptable to varying site conditions
- High axial and lateral loading capacity

Disadvantages of Bucket Foundations

- Extremely sensitive to construction procedures
- Not good for contaminated sites
- Lack of construction expertise
- Lack of Qualified Inspectors

Introduction

The basic function of the ocean mining system is to collect the mineral resources of the seafloor, lift them to the sea surface, and transfer them to the port. It is generally composed of four subsystems such as the undersea mining system, the lifting system, the control and power system, and the surface supporting system. The lifting system is the intermediate link between the seafloor mining

system and the surface supporting system. It is the channel to transfer the polymetallic nodules from the seafloor to the surface ship. Besides, it also acts as the carrier of power and signal cables and the heart of the ocean mining system (Fig. 1).

The buffer station is located in the middle of the lifting system. The upper end of the buffer station is connected to the deep-sea mining ship through the rigid riser, and the lower end is connected to the mining vehicle through the flexible riser.

Research Process

For deep-sea mining, many research institutions have done a lot of work in recent decades.

In March 1979, several international mining consortia countries, led by the United States, including Canada, the United Kingdom, West Germany, Belgium, the Netherlands, Italy, and Japan, etc., first adopted a deep-sea mining system with a buffer station to collect nodules from 5000 m seabed. Russia began to develop the deep-sea mining system with a buffer station in 1980. In 1991, the system design was completed and a 1/10 prototype test was carried out in 100–1000 m water depth of the Black

Sea (Wang 2015). Korea has been engaged in the development and research of deep-sea mineral resources since the 1990s. The conceptual design of the riser lifting system of the subsea collector with a buffer station and the structural design of the hydraulic mechanical composite ore collecting system with the lifting system were completed (Yoon 2011). In 2013, the system was tested in 1370 m deep-sea area, 130 km southeast of Puxiang in Qingshang North Road. Canada used a diaphragm positive displacement pump system as the underwater mineral lift pump, which plays a buffer role in the whole deep-sea mining lifting system (Smith 2011). The pump system consists of two pump modules, and each module includes five diaphragm pumps driven by the return water of mineral dehydration from mining vessels. In 2012, the underwater mineral lift pump was put into operation factory test evaluation, and some components were tested in 2500 m of water.

Chinese research institutions carried out basic research on deep-sea mining during “the 8th Five-Year Plan” period and proposed a hydraulic lifting deep-sea mining system with buffer function (Tang et al. 2013). An elastic blade wheel feeder was added to the buffer station during the “9th Five-Year Plan” period, which solved the problems of feeding jam, ore bin arching, and emergency discharging. In the “13th Five-Year Plan,” the buffer station of the deep-sea mining mineral lifting system was planned to complete the 1000 m sea trial in 2021 (Yang et al. 2020).

Buffer Station Component

Overview

The buffer station mainly includes an external frame, an internal equipment system, and a riser system. The external frame includes a swing connecting device, top frame, upper frame body, and the lower frame body. The internal equipment includes a storage bunker, hose pump, constant feeder, hydraulic pressure station, electronic lifting cabin, and power distribution box, etc. (Fig. 2).

Buffer Station, Fig. 2 Buffer station component system. (1) Swing connecting device; (2) top frame; (3) swing hose; (4) storage bunker; (5) power distribution box; (6) upper storage bunker; (7) constant feeder; (8) mixer; (9) hydraulic pressure station; (10) hose pump; (11) counterweight; (12) lower frame

Storage Bunker

The volume of the storage bunker is generally determined by the principle that it can continuously feed ores by the bunker if there are no nodules in the collection path in 15 min. The top of the bin is open and the lower part is conical, which is conducive to ores discharge and prevents ores from piling up.

The Constant Feeder

The constant feeder adopts an elastic blade feeder, which is composed of a shell, a rotor, a rotor support end cover, a hydraulic pressure motor, and a speed measuring device. The shell is processed by connecting the flange, the side plate, and the cylinder body. Its feed inlet is asymmetric and biased to one side of the feed port, to reduce the resistance moment of feeding. An arc-shaped baffle plate is fixed at the outlet to make the feed out. The feed port has a parallelogram shape so

that the material falls uniformly and continuously. The constant feeder can solve the blocking problem and achieve uniform feeding. The feeding fluctuation of ores is less than 5%.

Swing Connection Device

It is located at the top of the buffer station and connects the buffer station body to the rigid riser. It adopts the movable hinged form, which releases the swing of the buffer station body. It can optimize the stress condition of the riser system and improve the stability of the whole system. The flexible riser passes through the middle of the swing connection device and connects the buffer station to the upper rigid riser.

External Frame

The unsealed frame structure is adopted to protect the internal equipment and prevent the impact when placing and recycling. To facilitate the installation and maintenance, the external frame is modularly designed. It includes a top frame, an upper frame, and a bottom frame.

The Hose Pump

The ores are pumped from the deep-sea mining vehicle to the storage bunker of the buffer station through the flexible riser. The hose pump should have a robust characteristic.

The Function

The main functions are as follows.

The ores pretreatment function. The deep-sea ores collected by the mining machine are delivered to the buffer station's storage bunker. Then the ores are continuously and quantitatively feeds to the lifting pipe by a constant feeder. This will avoid the influence of ore concentration caused by the change of nodule abundance on the operation of the underwater transportation system. That will ensure the stability of the ore lifting process parameters and high lifting efficiency.

Providing EIP for mining underwater systems. For example, it can be used as a reference settlement unit of the acoustic positioning system.

Buffer Station, Fig. 3 Mining ore transportation procedure

The hydrodynamic optimization function.

The buffer station helps to keep the riser vertical and improves the DCOP. If the weight and shape are designed reasonably, the vertical displacement and axial stress of the riser system caused by ship heave may be reduced by 50% and 17%, respectively, according to the model test (Fig. 3).

Bare wire; Conductor; Insulation layer; Polyester rope; Power cable; Winding wire

Definition

An electric cable is usually made up of several or sets of wires twisted together. There is insulation between wires, with a layer of highly insulated cover enclosed outside. There are also shield and armor in some cables. Electric cables can be classified into the power cable and the communication cable. The former one is mainly used to provide electric power, and the latter one is mainly used

for transmission of power, control of electricity, and signal transmission (Limei 2016). Insulation is used to provide dielectric strength and electric insulation. There are sheathes in all cables which can protect the cables, making the cables round and adjusting the size and weight. Shield is mainly used for the function of shielding magnetic field. And armor plays an important role in strengthening (Hammons 2003).

Besides electric cable, polyester rope has been put into usage as part of mooring lines for two decades and more frequently used in deeper water globally (Mukoyama et al. 2006). Polyester cable is widely used in the mooring system of deep water due to its high strength, light weight, and good anti-fatigue performance, which is mainly consist of polyester, polypropylene, nylon, manila hemp, Dyneema, etc (Honjo 2001).

Scientific Fundamentals

Structure Composition of Electric Cable

This entry takes a typical structure of cable as an example, which contains conductor, insulation, sheath, and armor (Schmidt 2012). The effects they make in the cable are as follows (Fig. 1).

Conductor

Conductor is a component of conducting electric current, which is a vitally important core component in the structure of the electric cable and

Cable, Fig. 1 The structure of electric cable (http://www.orientcable.com/v_pros.asp?/5.html)

which determines the basic performance (Zuijderduin 2012). The specifications of the wires and cables are up to the cross section of the conductors, which are mainly made of high conductivity materials (copper or aluminum). According to the operating conditions of the required flexibility, each core may be twisted by a single wire or multiple wires of the electric cables (Zhong 2015). In general, bare copper wire, tin-plated copper wire, silver-plated copper wire, tin-copper alloy, enameled wire, copper wire, copper clad steel, and so on are the common conductors in the market (Xuyang 2017).

Insulation Layer

Insulation layer is used as the insulation material for electric cables. According to different requirements of the withstand voltage conditions, insulation materials are covered outside the conductors with different degree of thicknesses (Ouatah et al. 2013). Insulation layer usually has excellent insulation performance and heat resistance. Generally, the higher the voltage is, the thicker the insulation layer is, but it is not proportional. Usually, the insulation materials used in cables are oil-immersed paper, polyvinyl chloride, polyethylene, cross-linked polyethylene, rubber, and so on (Zhang 2015). Cables are often classified by insulation materials, namely, the oil-immersed paper-insulated cables, the PVC cables, and the cross-linked polyethylene cables.

Seal Sheath

Seal sheath can protect the wire core from damage caused by general external factors or other environmental factors, including machinery, water, moisture, chemicals, and light. Due to the insulation which is susceptible to moisture, the lead or aluminum extrusion seal sheath is generally used (Ohsaki et al. 2012).

Armor Layer

As a part of protecting electric cables, armor layer is used to protect seal sheath from mechanical damage. In general, galvanized steel tapes, steel wires, or copper belts and copper wires are used as armor wrapped around the sheath (so it is called armor cable). The armor layer can shield the electric field and can prevent from external electromagnetic interference (Dvorsky et al. 2011). In order to avoid the corrosion of steel tape and steel wire by the surrounding media, they are usually coated with asphalt or wrapped around a jute-immersed layer or extrusion polyethylene and PVC sheath.

Classification

Wires and cables can be generally classified into the following five categories according to different actual engineering uses.

Bare Wire

There are only conductors in bare wires, which have no insulation. Bare wire can be classified

into copper, aluminum and other metals, composite metal round-single wire and stranded wire, soft wiring, and transmission lines of various structures (Courty and Garo 2017).

Power Cable

Power cable is a wire product used in transmission and distribution of high power energy in the main line of power system, which includes power cables that have various kinds of voltage from 1 to 500 or above and various kinds of insulation, such as overhead bare wires, power cables (plastic power cables, oiled paper power cables which are almost replaced by the plastic power cables, rubber sheathed cables, overhead insulated cables), branch cables, electromagnetic wires, electrical equipment cables for electric power equipments, and so on (Grayson et al. 2001).

Wires and Cables for Electrical Equipments

There are various power cables whose wires and cables are for electrical equipments and which can transmit power directly from the distribution point of the power system to different electrical equipments. These cables are also applied in the electrical installation lines and control signal for kinds of industry and agriculture (Chen et al. 2012). The structures and performances should be determined in combination with the characteristics of the equipment and the environmental conditions, due to the extensive uses and different types of these cables.

Communication Cable and Optical Fiber Cable

Communication cable is used to transmit data and other telecommunication information in telephone, telegraph, television, radio, and fax. There are many kinds of wires and cables which are used in the information transmission system, such as telephone cables, television cables, electronic cables, radio-frequency cables, optical fiber cables, data cables, electromagnetic wires, power communication, and other composite cables.

Winding Wire

Winding wire is a conductive metallic wire with an insulation layer, which is used to produce coil or winding used for electrical products. Its

function is to generate a magnetic field by electric current or generate an inductive electric current by cutting the magnetic force line, which realizes the mutual conversion of electric and magnetic energy. That is why it is also called an electromagnetic wire (Bicen 2017).

Basic Property

As is known to all, breakdown often occurs during the electric cable operation. The so-called cable breakdown is the short circuit between the core wire of the inner conductor layer and the metal net on the ground under the high-voltage field after the insulation layer of the cable is punctured. And the short circuit of high-voltage secondary coil is formed on the circuit, which increases the secondary current. Cable breakdown is quite harmful, which will burn the cable directly, leading to serious economic loss and threatening production seriously. Many reasons contribute to the breakdown of cables in operation, and the main reasons are the reduction of cable performance and the damage caused by external forces. Therefore, the basic property indicators of cable are summarized as follows.

Shielding Property

In the process of signal transmission, unshielded cable has antenna effect, which not only radiates signals outward but also receives external signals. It is likely to form electromagnetic interference to the signal, which leads to the communication failure, increasing noise, signal error, and other influences. Therefore, cable itself has a certain shielding performance, which is very important in the process of cable operation. Shielding attenuation and transfer impedance are two important indexes to measure the shielding performance of cables. Shielding attenuation is based on electromagnetic field theory which reflects the shielding performances of cables directly. Transfer impedance is based on circuit theory which reflects the shielding performance of cables indirectly. Besides, the structure of conductor has a certain influence on the shielding performance of the cable, which can be enhanced by wearing the outer conductor or the smooth aluminum pipe outer conductor (Chen et al. 2017).

Voltage

Since electric cables can be used in power systems and signal transmission systems, the voltage of electric cables usually includes the voltage of power and signal cable. Apparently, the voltage of power cable is the source of power for the cable, and the voltage of signal cable can be used to transmit signals. There are three important indexes which can be used to measure the voltage of power cable and signal cable. The first one is the nominal power frequency voltage(U_0), which is between conductor and the ground or metal shield for cable design. Another one is the nominal power frequency voltage(U), which is between conductors for cable design. And the third one is the maximum of the maximum system voltage (U_m) in which the device can withstand. According to the ISO 13628-5/API Spec 17E, the voltages of electric cables are as follows:

For power cable, the selection of power cable voltage level ranges from 0 V to the nominal power frequency voltage.

$$\frac{U_0}{U(U_m)} = 3.6/6(7.2)kV(rms) \quad (1)$$

For signal cable voltage, the selection of signal cable voltage level ranges from 0 V to the nominal power frequency voltage.

$$\frac{U_0}{U(U_m)} = 0.6/1.0(1.2)kV(rms) \quad (2)$$

Electric Current

Electric current is the electricity flow that a cable line can be up to when transmitting power. Electric current must flow through the cable line in order to transmit electricity. The more currents flow through the line, the more power it transmits. The cable load flow can be called the cable long-term allowable load flow when the temperature of conductor reaches the long-term allowable working temperature under thermal stability conditions. As for the working conditions, the maximum load current which is required by the load must be less than the long-term allowable load flow of the conductor in the air. In accordance

with the relevant specific provisions, the maximum allowable load flow for each type of wire can be obtained. The property of conductor is the internal factor that affects the cable load flow, which can be increased by extending the area of the wire cores; using high conductive materials, insulation materials with good high-temperature resistance, and thermal conductivity; and reducing contact resistance. The environment is the external factor that affects the cable load flow, which can be increased by the reasonable increase of the wire spacing and the choosing of the appropriate place for laying.

Attenuation

Attenuation refers to the signal attenuation along the length of the cable. When signals pass through the cable, some of the signals can be converted to heat, and some of the signals will leak out of the cable through the external conductor. In most applications, there is the purpose of minimizing the attenuation or keeping it within budget. In general, the larger the diameter of the cable is, the less attenuation of the cable is. In another word, by increasing the size of cable, the attenuation can be reduced. In addition, the higher the temperature is, the more the attenuation is.

Direct Current Resistance

Direct current resistance is an important parameter in cable and all aspects of testing, which determines the quality level of the cable. To make it specific, it is possible to judge whether the cross-sectional area of conductor is consistent with the manufacturing specifications, whether the total conductivity of cable is qualified, and whether the conductor is broken.

Insulation Resistance

Insulation resistance is the most basic insulation index for electrical equipments and circuits. The greater the insulation value is, the less the current is, and the higher the insulation performance index is. General electric conductor has a small resistance value of only a few omega. However, the value of insulation resistance is relatively greater, at least dozens MΩ or above. The value

of the insulation resistance varies due to the changes of the temperature and the length of cable. Therefore, it is calculated with the electric resistance converted to 20°C per unit length generally for comparison (Dian 2016).

Mechanical Property

In general, the properties, such as tensile strength, elongation, bending, flexibility, softness, shock resistance, wear resistance, and mechanical impact resistance, are the main mechanical properties. If the mechanical property cannot meet the actual working strength, the electric cable will be damaged.

Polyester Rope

Generally, there are three layers in a polyester rope with the outer layer as a braided protective layer, which is wear-resistant and protects the core rope. The secondary outer layer is a filter layer, which prevents particles of 3–5 μm or larger from entering the cable to cause wear and tear. The inner layer is a polyester core rope, which is subjected to tensile force. In addition, there can be two protective layers in the outer layer and two filter layers in the secondary outer layer according to the requirements of customers (Kim et al. 2013).

There are some advantages of polyester rope as follows: light weight, which can reduce the weight of the mooring system and increase the efficiency of the mooring level; low cost, much lower than steel cable; excellent in seawater corrosion resistance and no corrosion in seawater; and its fatigue performance which is much better than steel cable from experimental results. It also provides high strength and strength/quality ratio. Disadvantages of polyester rope are concluded as short application history, non-wear resistance, easy damage, and significant nonlinearity of stiffness.

Key Applications

An electric cable is made up of conductor, insulation, sheath, and so on, which can be used for

communication, power, and other related transmission and which are installed in the air, underground, or subsea. In fact, the distinction between cables and wires is not very strict. Usually the diameter and core of the wires are small, and the structure is simple. The wires without insulation and sheath are called naked wires. And the others are called electric cables (Calmet et al. 2002).

In 1879, it was an American inventor named Thomas Edison who wrapped jute around a copper rod, put it into an iron pipe, and filled in an asphalt mixture to form an electric cable. It was this man who laid this cable in New York, which pioneered the underground transmission of electricity. The next year, Cattender from Britain invented a power cable of insulation with bituminous impregnated paper. In 1908, a 20-KV cable network was built in Britain, which made the application of power cable more and more extensive. Three years later, a high-voltage cable with 60 KV was laid in Germany, indicating the scientific revolution of high-voltage cables. Since 1979, ultra-high-voltage cables of cross-link have been put into trial operation in Japan, Finland, Sweden, and Norway. Electric cables have been used for more than 100 years, which have been playing an important role in communication up to now with the development of the information technology.

In addition to transmitting electricity, electric cables are also indispensable in communication. In 1839, Cook and Wheatstone built the first 21-kilometer-length telegraph line in London. The first subsea cable in the world was laid across the English Channel between England and France by John Watkins Brett in 1850. But a fisherman mistakenly thought that he had found a big fish and pulled the cable out of the subsea. The following year, Brett laid the cable again and succeeded finally, meaning the UK and the European continent were connected with each other successfully (Fig. 2).

The world's first transoceanic subsea cable was laid successfully by an American rich businessman named Cyrus West Field in 1866. He began this project since 1854, and it lasted more than 10 years, which experienced four failures. In

1876, thanks to the invention of telephone by Bell, it began to accelerate the laying of subsea cables on a large scale around the world. Until 1902, the global submarine communication cable system was completed basically. Ever

since, communication cables have developed rapidly in western countries and spread among big cities, which reached a climax after the 1920s, and many countries have realized connections with communication cables between each other (Fig. 3).

Polyester rope mooring systems have been widely used around the world, especially in the waters of Brazil and the Gulf of Mexico. Brazilian State Oil Company began to use experimental polyester rope in 1995 for the first time and replaced within 2-year period. The first practical application was an external mooring buoy by Brazilian State Oil Company in 1997.

As mentioned above, electric cables have been used for more than 100 years, which were used to transmit electricity originally. Electric cables played an important role in communication up to now with the development of the information technology. Power system used in wire and cable products mainly includes overhead bare wires, power cables (plastic cables, rubber sets of cables, overhead insulated cables), electromagnetic wires, and power equipments with electrical wire and cable equipment, etc. In addition, the main wires and cables used in the information transmission system are municipal telephone cables, TV cables, electronic cables, radio-frequency cables, optical fiber cables, data cables, electromagnetic cables, power communication cables, and other composite cables.

Capacity of Suction Anchor

Dengfeng Fu
 State Key Laboratory of Hydraulic Engineering Simulation and Safety, Tianjin University,
 Tianjin, China

Definition

The suction anchors are usually cylindrical units with large diameter (D of 3–8 m), open at the

bottom and closed at the top, and generally with an aspect ratio (length to diameter, L/D) of two to six. The anchoring line is connected to the padeye attached to the side of the caisson at a depth down the mudline. The capacity of suction anchor is therefore the ability to resist the permanent and environmental loading from the anchor line during the operational conditions.

Failure Mechanism

The capacity of suction anchor is highly dependence of soil plasticity flow around the foundation. Many influential factors, especially for the complicated boundary conditions, such as anchor geometry, type of mooring system (loading direction and magnitude), installation performance, soil conditions, time after installation, durations of applied sustained loading, cycles of loading, etc., should be explicitly accounted for to investigate the failure mechanism.

In the following subsections, the typical failure mechanisms under uniaxial (including mainly vertical and horizontal) and inclined loading are discussed.

Under Vertical Uplift Loading

Under conditions of pure uplift loading, three failure mechanisms have been identified by a

number of experimental or numerical analyses: three important components of failure modes including reverse end bearing failure, sliding failure and tensile failure, as illustrated in Fig. 1.

Reverse End Bearing Failure

Reverse end bearing failure can be relied upon for a suction anchor if the top cap is sealed and the soil response is undrained, typically when the anchor is subjected to short-term (transient) loading. Passive suction is generated in the anchor, so that the soil plug is pulled out together with the caisson. The failure mode at the bottom during uplift was similar to that during compression and was referred to as “a reverse end bearing mechanism.”

Sliding Failure

When suction anchor is subjected to a sustained (drained) loading or the anchor lid is vented, reverse end bearing cannot be generated, and the failure occurs along the internal and external skirt.

Tensile Failure

When partially drained condition prevails, such as when the suction anchor is pulled out at intermediate rates, passive suction may be generated partially, so that the caisson and the internal soil plug tends to detach from the soil below the caisson.

Capacity of Suction Anchor, Fig. 1 Failure mechanisms for vertical pullout resistance (a) reverse end bearing, under undrained conditions; (b) caisson pullout, under

drained conditions; (c) caisson and plug pullout, under partially drained conditions

Under Optimal Horizontal Loading

The suction anchors under pure horizontal loading is rarely found offshore, while drag angle at the padeye is typically at a small angle of 10° – 20° in the catenary mooring system. Meanwhile, the padeye position is often optimized in design, allowing the anchor to slide horizontally with minimal rotation.

As shown in Fig. 2, the corresponding failure mechanism for lateral capacity of the suction anchor is considered to be similar to those for laterally load piles (Murff and Hamilton 1993) that a passive/active conical wedge extending from the edge of the caisson at shallow depth to the seabed dominating the soil mechanism; and a confined flow region is assumed below the wedge with the center of rotation locating below the anchor tip (Martin and Randolph 2006). For caissons loaded above the optimal depth, an external scoop mechanism can replace the flow region, with the center of rotation locating within the anchor.

Under Inclined Loading

The failure mechanism under inclined loading depends on the position of the centerline intercept for the applied load (varying with padeye position and loading angle), the length of the suction anchor, and the soil properties (Supachawarote 2006). The impact of tensile crack on the failure mechanism is examined by Fu et al. (2020).

The maximum holding capacity is obtained if the chain is attached at a depth where the anchor moves largely in horizontal translation with minimal rotation. This is called the “optimal padeye depth.”

When the centerline intercept is located above the optimal padeye position, the anchor rotates forward, and combinations of wedge flow around and full circular rotational failure were observed. For the short anchor, the wedge and rotational flow mechanisms were observed, without the flow around region. For the longer anchor, the flow around region increasingly dominates.

While when the centerline intercept is located below the optimal padeye position, a backward rotation was observed, and the rotational flow failure extends to the mudline. And with the centerline loading point moves deeper, the full circular rotational failure eventually moves below the soil surface, which is evident for anchor with increasing length. For long anchor, the circular rotational flow failure is only observed below the tip of the anchors; and only combination of the wedge and flow around mechanisms was observed within the anchor length.

Design Method of Evaluating Capacity

The load capacity of a suction caisson anchor, assuming a sealed cap, is derived from bearing

Capacity of Suction Anchor, Fig. 2 Soil failure mechanism for suction anchor (a) conical wedge and flow region and (b) external base rotational scoop. (After Randolph and House 2001)

resistance between the soil and the projected area of the caisson (on a vertical plane for horizontal resistance and the cross-sectional area for reverse end bearing), aided by frictional resistance along the outside of the caisson shaft. Reverse end bearing relies on passive suctions developed within the soil plug, and so consideration needs to be given to the time over which these can be sustained.

Vertical Uplift Capacity

Equation

The vertical pullout capacity is equal to one of the following depending on the drainage conditions (essentially whether the passive suction is sustained during loading):

- (a) For undrained conditions, with a non-dimensional diameter $T_k (= c_v/vD$, where c_v is the consolidation coefficient, v is the loading velocity, D is the diameter of the anchor) recommended to be less than 0.002 (Deng and Carter 2000), the passive suction is thought to be sustained during loading

$$V_{ult} = W' + A_{se}\alpha_e\bar{s}_{u(t)} + N_c s_u A_e \quad (1)$$

- (b) For drained condition, ($T_k > 0.6$), the passive suction is not generated during loading

$$V_{ult} = W' + A_{se}\alpha_e\bar{s}_{u(t)} + A_{si}\alpha_i\bar{s}_{u(t)} \quad (2)$$

- (c) For partially drained condition ($0.002 < T_k < 0.6$), passive suction is partially generated

$$V_{ult} = W' + A_{se}\alpha_e\bar{s}_{u(t)} + W'_{plug} \quad (3)$$

where A_{se} and A_{si} are the external and internal shaft surface area, A_e is the external cross-sectional area, α_e and α_i are the coefficient of external and internal shaft friction, N_c is the reverse end bearing factor, s_u is the undrained shear strength at tip level, $\bar{s}_{u(t)}$ is the average

undrained shear strength over penetrated depth at time t after installation, W'_{plug} is the effective weight of the soil plug, and W' is the submerged caisson weight.

Evaluation of Parameters α and N_c

The soil shear strength around the anchor is thought to be remold due to disturbance during skirt penetration during self-weight penetration. And this strength recovers later with time following installation, due to a combination of thixotropy and consolidation (Andersen et al. 2005), which however remains below the intact undrained shear strength. This process is referred as “setup” and has been expressed conveniently with α_s , with $\alpha < 1$. A base value of α of 0.65 was proposed for suction caisson design (Anderson and Jostad 2004), subjected to their specific soil properties. The shaft friction depends on the anchor surface roughness, soil type, and over-consolidation ratio. And Chen et al. (2009) suggests method of installation (referring jacking or suction installation) leads to negligible difference in α based on the centrifuge and LDFE numerical studies. And their results also suggest α of 15–20% lower than those recommended by the American Petroleum Institute (API) for driven piles in normally consolidated clays. It should also be noted that lower values of friction coefficient for internal shaft friction compared with external friction were reported in the model tests conducted on double-walled caisson (Jeanjean 2006).

The reverse end bearing N_c is a function of soil property and the aspect ratio (L/D) of the anchor. For an anchor with L/D of 2 in the over-consolidated kaolin clay, Fuglsang and Steensen-Bach (1991) reported the centrifuge and laboratory tests, suggesting the reverse bearing capacity factors varying between 6.5 and 8.5. This is lower than the theoretical lower bound results of 9.2 for the caisson with L/D of 2 (Martin 2001). Other centrifuge tests for the anchor with the same aspect ratio (Clukey and Morrison 1993) suggested that reverse end bearing is around 11. This high magnitude of N_c may be related to the vane shear strength adopted for the interpretation, which leads to an overestimation of 25% (Watson

et al. 2000). Considering the loading mode (monotonic transient loading, cyclic loading, and long-term sustained loading), the reverse end bearing falls in a wider range of 9.1–14.6 (Randolph and House 2001). And a conservative N_c value of 9 is suggested to be taken, due to the strain-softening nature of the response as the caisson is extracted. A bearing capacity factor of $N_c = 9$ irrespective of the aspect ratio for suction anchor is also suggested by El-Gharbawy and Olson based on the results of the laboratory tests in kaolin clay. And by contrast, an N_c value of 12 is found to be mobilized at large displacements (Jeanjean 2006), although values of around 9 were mobilized at the displacement where peak external shaft friction was achieved. Hence it is rational to take N_c as of 9 is appropriate.

Optimal Horizontal Capacity

Equation

Assuming the padeye is positioned at the optimum level and pure translation failure occurs, the maximum horizontal resistance is

$$H_{\max} = LD_e N_p \bar{s}_u \quad (4)$$

where L is the embedded length of caisson, D_e is the external diameter of the caisson, N_p is the lateral bearing capacity factor, and $\bar{s}_u$ is the average undrained shear strength over penetrated depth.

Evaluation of Parameters N_p

Zhang et al. (2016) recommended the following approach to calculate the lateral bearing capacity factor

$$\begin{aligned} N_{p0} &= N_1 \\ &- (N_1 - N_2) \left[1 - \left(\frac{z/D}{Z} \right)^{0.6} \right]^{1.35} \\ &- (1 - \alpha) \\ &\leq N_{pd} \end{aligned} \quad (5)$$

where

$$N_1 = 11.94 \quad (6)$$

$$N_2 = 3.22 \quad (7)$$

$$Z = 16.8 - 2.3 \lg \lambda \geq 14.5 \quad (8)$$

$$\lambda = \frac{s_{um}}{kD} \quad (9)$$

$$N_{pd} = 9.14 + 2.8\alpha \quad (10)$$

In Eq. 8, Z stands for the normalized depth (z/D) at which the soil failure mechanism transits from the wedge failure to the localized flow around failure for a fully rough soil-pile interface in idealized weightless soil. The value of Z is related to the normalized strength homogeneity parameter λ . N_{pd} stands for the limiting bearing capacity factor mobilized in a localized flow-around mechanism, expressed as a function of the interface roughness factor α ($0 \leq \alpha \leq 1$), according to the plasticity solution.

Inclined Load Capacity

In the presence of both vertical and horizontal loading, a reduction occurs in the pure vertical and horizontal capacities, as the caisson is simultaneously displaced vertically and laterally (or rotated). Clukey et al. (2003) suggested for the loading angles applied by the catenary mooring line system, which are generally less than 20° from the horizontal, the caisson capacity is dominated by the horizontal capacity, and the capacity may be estimated by the capacity under pure translation divided by the cosine of the loading angle at the padeye. Conversely for high loading angles from the horizontal applied by taut and semi-taut mooring systems (generally in excess of 30°), the caisson capacity is essentially governed by the vertical capacity of the caisson and maybe approximately taken as the vertical capacity divided by the sine of the loading angle.

For the more general cases, the interaction between vertical and horizontal loading may be conveniently modelled as a failure envelope in the combined vertical-horizontal load space, which was found to vary with the aspect ratio (L/D), location, and direction of the applied load. The shape of the failure envelopes for suction anchor may be modelled by an elliptical relationship

$$\left(\frac{H}{H_{ult}}\right)^a + \left(\frac{V}{V_{ult}}\right)^b = 1 \quad (11)$$

where H_{ult} and V_{ult} are the uniaxial horizontal and vertical capacities, respectively, and the exponents a and b vary with caisson aspect ratio L/D according to Supachawarote (2006).

$$a = \frac{L}{D} + 0.5 \quad (12)$$

$$b = -\frac{L}{3D} + 4.5 \quad (13)$$

The sensitivity of caisson capacity to the changes in padeye position or loading angle was also investigated using the three-dimensional finite element analysis, limit equilibrium solutions upper bound limit analyses, profiles of lateral resistance based on Murff and Hamilton (1993), and centrifuge modelling (Clukey et al. 2003). It was found that the variation of centerline intercept for the applied load (varying with padeye position and loading angle) results in the large discrepancy of the capacity. As shown in Fig. 3, the centerline loading depth around 0.7 gives the largest capacity. With the shift of the padeye position and loading angle, the capacity reduces gradually within the depth of $\pm 0.15 L$ from the optimal centerline location and reduces sharply beyond this range.

Capacity of Suction Anchor, Fig. 3 Effect of padeye depth on capacity. (After Andersen et al. 2005)

Consideration in Design

The Effect of Crack on the Suction Anchor Capacity

The inclined load capacity of a suction anchor will also depend on whether a crack develops along the trailing edge of the caisson. A crack is normally formed for suction anchors with a long aspect ratio in over-consolidated soils. The finite element results (Fu et al. 2020) show a reduction of up to 50% for any loading angle (the reduction is mainly found at the optimal padeye depth and maintained for loading angles of up to about 45° for $L/D = 1.5, 2$, and 3 in homogeneous soil).

Considering Site Conditions

Some changes in site conditions should be explicitly accounted for in the design of geotechnical capacity of suction anchor. The soil scour around a suction foundation is an important scenario in design, where the soil migration around foundation might occur under the wave and current loading. The volume of soil mobilized by foundation is therefore changed, resulting in a significant decrease in capacity. In some cases, the shallow gas accumulation inside a suction foundation also should be given attention (Gylland and de Vries 2008). Additionally, the trenching is another issue and most likely to occur particularly when using semi-taut to taut mooring configurations with caisson employed in the soft deposits. Considerable motion of ground chain could lead to the remolded softening and erosion of soil particles, forming a curved trench in the vicinity of foundation. O'Neill et al. (2018) presented a method to interpret and estimate the primary mechanism of trenching development.

Considering Cyclic Loading Effect

Offshore foundations are often cyclically loaded in both calm sea condition and extreme events (i.e., storm or hurricane event). For suction anchor, the cyclic wind, wave, current, and structural loadings are transferred to the foundation by mooring lines. It gives rise to pore pressure accumulation for soil around foundation, which is one of the principle concerns in design of foundation's capacity. Regarding clay, the strain softening may occur as the pore pressure accumulates, and both

soil stiffness and strength can significantly reduce. Regarding sands, the earlier densification may occur during cyclic loading, then pore pressure starts accumulating, and finally a state of liquefaction may be present with the effective stress of soil almost being zero. Therefore, the continual buildup of excess pore pressure in soil under cyclic loading potentially results in a significant decrease in capacity of foundation.

Based on laboratory cyclic triaxial (TA) and direct simple shear (DSS) tests, Andersen (2015) presented a method to assess the accumulation of pore pressure, which is dependence of cyclic shear ratio τ_{cy}/σ'_{vc} . τ_{cy} is the cyclic shear stress (kPa), and σ'_{vc} is the vertical consolidation pressure (kPa). The corresponding cyclic shear strength $\tau_{cy,f}$ at failure was indicated using a strain contour diagram, with the equivalent number of cycles to failure captured at the permanent cyclic shear strain of 15%. Besides, many soil models based on the critical soil mechanics theory were numerically developed in the last three decades, to describe and interpret the cyclic behavior of soil. However, no constitutive model has been developed to date, enabling to represent all the key characteristics of cyclic soil response, as many factors may influence the cyclic performance of soil, i.e., cyclic stress level, loading frequency, over-consolidation ratio, static pre-shearing, etc. In practice, the alternative option available for engineers is choosing a soil material factor (ISO 2016) or considering the uncertainty by a partial factor of capacity (ISO 2016), when the cyclic loading effect is necessary to be considered.

Considering Reconsolidation Effect

For suction anchor, an allowable duration is often found after its installation, e.g., 3 to 6 months. This gives an opportunity for consolidation under self-weight prior to commencing operations. During consolidation, the excess pore pressures generated by the self-weight preloading dissipate reducing the void ratio of soil and enhancing the soil strength, hence increasing the foundation capacity. It is notable that the dissipation of pore pressure also occurs during the cyclic loading condition, as the pore pressures in fact generated during a cyclic duration and will

dissipate in the subsequent cycles. The appropriate consideration of reconsolidation in service design is necessary to develop a reliable and economical method.

From some centrifuge model tests (Bienen et al. 2010; Fu et al. 2015), the significant increase in bearing capacity of a preloaded foundation in clay was found, for instance, a gain in bearing capacity of 30% after 10% of consolidation and a doubling after 80% of consolidation under a vertical preload of 50% of the ultimate vertical load.

Notation

a	Parameter depending on L/D
A_e	External cross-sectional area

Definition

A typical CALM system consists of the mooring buoy, chain and anchor system, mooring assemblies, and floating and submarine hose strings. The buoy body provides the necessary buoyancy to keep the system afloat. A rotating deck or turntable is mounted on top of the buoy body to transmit mooring force from the mooring assemblies through the buoy to the anchor chains. The CALM anchoring system consists of 4–8 anchor chains extending from the buoy body radially out and terminating at firmly embedded anchors or anchor piles (Luo et al. 2015).

Scientific Fundamentals

System Composition

The CALM system consists of a large buoy, which supports a number of catenary chain legs anchored to the sea floor (Fig. 1). Riser systems or flow lines that emerge from the sea floor are attached to the underside of the CALM buoy. Some of the systems use a hawser, typically a synthetic rope, between the vessel and the buoy. Since the response of the CALM buoy is totally different than that of the vessel under the influence of waves, this system is limited in its ability to withstand environmental conditions. When sea states attain a certain magnitude, it is necessary to cast the vessel off. In order to overcome this limitation, rigid structural yokes with articulations are used in some designs to tie the vessel to the top of the buoy (Vryhof 2005).

CALM system can be used both in shallow water and deepwater area and are connected to a shore storage facility (tank farm) or to offshore production platforms by means of a submarine pipeline. For this application, the CALM is used as an offloading system for a deepwater Floating Production Storage and Offloading unit (FPSO).

CALM is also a complex nonlinear system for oil tanker or FPSO. In addition to the three degrees of freedom in the horizontal plane (surge, sway and yaw), the entire external transmission

system has 12 degrees of freedom (buoys 6, tanker or FPSO 6) of the motion response. If the simultaneous CALM system-FPSO-the coupling motion analysis of the tanker, it will reach 18 degrees of freedom. Because the incident wave period is generally greater than 8 s, the longitudinal oscillation is the main motion form of the buoy. Therefore, it is necessary to take into account the pitching motion characteristics of single point mooring system in the design of pipeline (SBM 2012).

The CALM system allows the moored tanker to weathervane. With this principle, the tanker offers to the environment (waves, current, and wind), a direction of least resistance, thus the system can operate in much higher conditions than the other systems. The CALM system reacts against the force created by the environment on the moored tanker by a set of two spring effects: (a) The nylon mooring hawser, (b) The buoy mooring legs, which are installed in a Catenary configuration (GL 2014).

CALM-catenary anchor leg mooring can be capable of handling very large crude carriers. This configuration uses six or eight heavy anchor chains placed radially around the buoy, of a tonnage to suit the designed load, and attached to an anchor or pile to provide the required holding power. The anchor chains are pre-tensioned to ensure that the buoy is held in position above the PLEM. As the load from the tanker is applied, the heavy chains on the far side straighten and lift off the seabed to apply the balancing load. Under full design load, there is still some meters of chain lying on the bottom. The flexible hose riser may be in one of three basic configurations, all designed to accommodate tidal depth variation and lateral displacement due to mooring loads. In all cases, the hose curvature changes to accommodate lateral and vertical movement of the buoy, and the hoses are supported at near neutral buoyancy by floats along the length (Chakrabarti 2005). These are

- Chinese lantern, in which two to four mirror symmetrical hoses connect the PLEM with the buoy, with the convexity of the curve facing radially outwards.

Catenary Anchor Leg Mooring, Fig. 1 CALM (www.sbmoffshore.com, 2012)

- Lazy-S, in which the riser hose leaves the PLEM at a steep angle, then flattens out before gradually curving upwards to meet the buoy approximately vertically, in a flattened S-curve.
- Steep-S, in which the hose first rises roughly vertically to a submerged float, before making a sharp bend downwards followed by a slow curve through horizontal to a vertical attachment to the buoy (API RP 2SK 1993).

Historical Development

The history of mooring system started from the development and use of the single point mooring device of catenary buoy by the US navy during World War II, and then developed rapidly. Numerous different mooring systems have been developed over the years (Kent et al. 2007).

The world's earliest single point mooring system is CALM. CALM mooring system is the most widely used single mooring. There are over

560 single point mooring system over the world. And there are about 500 CALM systems by 2008. In 1997, a polyester rope + anchor chain catenary mooring system is first used for a FPSO in Brazil. Afterwards, more and more fiber mooring systems appeared in the Gulf of Mexico (Winkler and Mckenna 1994). Since early 2000, the CALM design has been used and adapted to deepwater conditions, greater than 1,000 m (ABS 2014). Installed CALM in deepwater are listed as following: Agbami (Nigeria, 1435 m), Kizomba A&B (Angola, 1200 m, 1000 m), Dalia (Angola, 1341 m), Erha (Nigeria, 1190 m), Akpo (Nigeria, 1285 m), Bonga (Nigeria, 1000 m), Girassol (Angola, 1320 m), Greater Plutonio (Angola, 1310 m).

Key Technology in the Development of CALM

Since the 1970s, the research on the CALM system can be divided into the following two aspects: (1) engineering design – the deploy/recovery of mooring system, the composition of mooring line, the arrangement of mooring system, and the development of anchor. (2) theoretical research – environmental load, static analysis of anchor mooring line, dynamic response between mooring system and mooring floating body.

Haixiao Liu et al. (2014) used a specially designed experimental system to investigate the nonlinear mechanical behavior of synthetic fiber cables, including how stiffness changes, how the main factors affect the hydrodynamic stiffness changes, and the nonlinear tension-elongation relationship. The similarity criterion of the hydrodynamic stiffness of fiber cables derives from scale analysis and experiments verification. The accuracy of empirical expressions for hydrodynamic stiffness currently used is verified by measured data. The results show that the uniform load is an important factor affecting the hydrodynamic stiffness, and the effect of the amplitude of strain change on the stiffness cannot be ignored. The cyclic load is also an important factor affecting the hydrodynamic stiffness. Based on the measured data, an empirical expression considering both uniform load, strain amplitude, and the number of cyclic loads is presented.

It is the only expression that can evaluate the change of hydrodynamic stiffness under long-term cyclic loading.

Minzhe Li (2013) designed a mooring system for semi-platform by combining the semi-physical simulation and mooring system control method, to control the mooring line retracting and deploying to realize platform positioning and to detect the positioning effect under different sea conditions.

Amir G. Salem et al. (2012) studied the method of estimating pitch motion of CALM system in frequency domain and verified it by experiment. The hydrodynamics of CALM system is directly related to the fatigue life of the mooring system under the coupling interaction of the mooring line and the oil pipeline. It is very important to accurately predict the hydrodynamic response of the buoy.

H. S. Da Costa Mattos and Chimisso (2011) studied the image model of creep test for low-density and high-strength HMPE fibers. In the macroscopic method, besides the traditional variables (pressure, total strain), scalar variables related to damage induced by creep process are introduced, and the evolution law of the damage variable is proposed. The life and elongation of HMPE specimens were predicted by creep tests at different loading levels and room temperature, which were in good agreement with the experimental results.

Davies P et al. (2011) studies the effects of uniform load, load range, and stiffness loading frequency on synthetic fiber cable including polyester cable, aramid cable, and HMPE in dry environment experimentally. In subsequent experiments, the bending stiffness of aramid cable and HMPE cable and the operation in deep water were discussed.

Meng Yuan (2010) used finite element time-domain method to construct the numerical calculation model of mooring cable for single-point and multi-point mooring system. Given a sinusoidal movement at the top of SPM system, the dynamic response of the whole mooring line was calculated. Taking the multi-point mooring system of Spar platform as an example, the time-history variation of the tension at the end of the mooring

line was calculated. The theoretical calculation results are consistent with the model test.

Francois and Davies (2008) carried out a sampling polyester cable test of cable with breaking strength of 70 tons and a full-scale test with the breaking strength of 800 tons. Viscoelastic response of the cable is considered for the quasi-static stiffness to reduce the change of uniformly distributed load under changing environmental conditions. The upper and lower boundaries of stiffness only considered the effect of uniformly distributed load.

Jing He (2007) used single-objective and multi-objective optimization methods to optimize the length, material price, and fracture strength of the two-component catenary mooring line of CALM system.

Y. T. Chai et al. (2002) proposed a semi-analytical quasi-stationary method based on catenary equation to deal with the interaction between the three-dimensional multi-mooring line partial subsection state and all subsection suspension state and the seabed, which can efficiently analyze the parameters of multi-point mooring system and flexible riser under different states.

Casey and Banfield (2002) investigates polyester cables with hydrodynamic axial stiffness ranging from 600 to 1000 tons, and points out that the strain amplitude is indeed a variable affecting the hydrodynamic stiffness.

Fernandes et al. (1999) carried out a full-scale polyester cable test with a diameter of 0.127 m. It is found that the dependence of hydrodynamic stiffness on frequency is weak.

Key Applications

The CALM is the most popular and widely used type of offshore loading terminal. CALMs have been deployed worldwide for a variety of applications, water depths, and vessel sizes ranging from small product carriers to Very Large Crude Carriers (VLCC). Because of safe and easy berthing and un-berthing operations, the CALM is equally the preferred offshore terminal of Mooring Masters and Tanker Captains (Luo et al. 2015).

CALM type single point is divided into the earliest Wheel CALM type, Turntable CALM type, and the newly developed Turret CALM type. At present, the most commonly used type is Turntable CALM. Compared with Wheel CALM, it uses large diameter rolling bearing at the center of the buoy to replace Bogey Wheel and transfer mooring force. In this way, the liquid rotary joint is completely independent of the turntable and bearing structure and no longer acts as a bearing member. The single point in this form consists of the following parts: buoy body, rotary turntable device, pipeline system and liquid rotary joint, anchor system, pipe manifold baseplate, underwater hose and floating hose, mooring rope device, and auxiliary equipment. The schematic diagram of the three types of buoy structure is shown in Fig. 2 (BV 2006).

The CALM system has no restrictions on the size of the tanker, is easy to maneuver, works around the clock, requires the least staff, and has strong adaptability to the environment. The advantages of the CALM system can be summarized as follows:

Catenary Anchor Leg Mooring, Fig. 2 Schematic diagram of the three types of buoy structure (www.sbmooffshore.com, 2012)

1. There is no need for a natural and excellent deep-water port, and there is no need for fixed dock facilities to provide loading and unloading operations.
2. The system is of lower cost.
3. It can be installed in open sea areas that do not require protection.
4. Can work normally all the year round.
5. Easy to install.
6. The mooring system is simple.
7. It can transmit a variety of oil and gas products at the same time.
8. The shuttle tanker has its own mooring propulsion system.
9. The terminal does not require a special tugboat for berthing and offshore, only a smaller vessel is required to serve (Luo et al. 2015).

Introduction

Mooring systems have been around just as long as man has felt the need for anchoring a floating structure at sea. These systems were used, and are still used, on ships and consisted of one or more lines connected to the bow or stern of the ship. Generally, the ships stay moored for a short duration of time (days). When the exploration and production of oil and gas started offshore, a need for more permanent mooring systems became apparent. Due to the demand for marine resource development, a large number of new floating structures have been designed and constructed, and various mooring systems have been emerged over the years; the catenary mooring system is a common and traditional way of locating floating structures, and several pretension mooring lines are arrayed around the structure to hold it in the desired location (Fig. 1).

Definition

It gets its name from the shape of the free hanging line, one end of the mooring line is connected to the floating structure, and the other end is fixed at the anchor point of the seabed; the part that is suspended in the seawater will take a catenary shape, which is similar to the rope that is fixed at both ends and freely placed under the uniform force. The catenary forms can be seen everywhere in nature; when you wake up in the morning to see spider webs covered with water drops, when you

see the ropes on the suspension bridge, and when you see the wires between the two poles, you know what kind of shape are they? The answer is the catenary. As early as 1690, Jacobi Bernoulli proposed the famous “catenary problem,” but it was not until Newton and Leibniz invented the calculus to get the correct answer. The catenary is a magical curve that has been used extensively in buildings, bridges, ship, and ocean platform moorings (Wren et al. 1989).

In marine engineering, spread catenary mooring systems and single-point catenary mooring systems are two common arrangements (Skop 1988). Mono-hull ship and semisubmersible platforms have traditionally been moored using a spread catenary mooring system, and the points are connected to different positions on the platform so that the platform cannot rotate freely, and the orientation of the platform remains basically unchanged. In some cases, excessive displacement caused by environmental forces may cause large loads on the mooring system. In order to overcome this drawback, a single-point mooring system has been developed which is characterized in that a plurality of mooring lines are connected at a point on the longitudinal centerline of the platform. The platform will have a wind vane effect to reduce the environmental loads caused by wind, current, and waves. Single-point moorings are used primarily for ship-shaped vessels. They allow the vessel to weather vane. This is necessary to minimize environmental loads on the ship-shaped vessel by heading into the prevailing weather (API 2005).

As can be seen from the above (Fig. 1), the catenary mooring system occupies a large range on the seabed, that is, the radius of influence of the mooring point will be large. In actual ocean engineering, the collision problem has to be considered with other structures, such as risers, conveyor cables, etc. At the seabed, the catenary mooring line lies horizontally, in general, which has a minimum length of 50 m; thus the mooring line has to be longer than the water depth, and the anchor points in a catenary mooring system only bear horizontal forces and are not subject to vertical forces (Fig. 2); the nonlinear restoring force generated by the catenary mooring system provides

Catenary Mooring, Fig. 1 The catenary mooring system of a semisubmersible platform. (From anchor manual 2005)

Catenary Mooring,
Fig. 2 The catenary
mooring line

the positioning function of the floating platform and balances the environmental load acting on the water platform (Samad 2009). Meanwhile, as the water depth increases, the length and weight of the mooring line also increase rapidly, which not only increases the tension in the chain but also increases the vertical load on the floating structure, further reducing the payload capacity of the floating structure. In that case, synthetic ropes are used because of conventional catenary systems become less and less economical (Banfield and Flory 2009). That is to say, the catenary mooring system is suitable for relatively shallow waters (<1000 m).

Theoretical Analysis Methods

For the mooring line of the general floating structure, it is not completely consistent with the theoretical catenary due to its own tensile, bending, and sea flow forces. However, for the convenience

Catenary Mooring, Fig. 3 Static analysis of catenary
mooring line

of calculation and analysis, the catenary theory is still used to describe its preliminary analysis and ignore the influence of sea current and wave, which is static analysis. Figure 3 shows catenary mooring line and its two-dimensional diagram of the force. The angle j is the angle between the mooring line at the fairlead and the horizontal; a

segment of arc microelement is selected from the catenary mooring line.

Depending on the water depth, the weight of the mooring line, and the force applied to the mooring line at the fairlead, the length of the suspended mooring line S in [m] can be calculated with:

$$S = \sqrt{d} \cdot \left(\frac{2 \cdot F}{w} - d \right)$$

with

d : the water depth plus the distance between sea level and the fairlead in [m]

F : the force applied to the mooring line at the fairlead in [t]

S : the unit weight of the mooring line in water in [t/m]

The horizontal distance X in [m] between the fairlead and the touchdown point of the mooring line on the seabed can be calculated with:

$$X = \left(\frac{F}{w} - d \right) \cdot \ln \left(\frac{S + \frac{F}{w}}{\frac{F}{w} - d} \right)$$

The weight of the suspended chain V in [t] is given by:

$$V = w \cdot S$$

The vertical distance of a catenary mooring line is given by the function:

$$y = -\frac{T_0}{w} \left[\cosh \left(\frac{wS}{T_0} \right) - 1 \right]$$

According to the above formula based on single-component mooring line, the shape and force of the catenary mooring line can be preliminarily calculated. However, mooring lines are usually composed of materials with many different properties, the calculation principle is the same, but the equations of the individual components need to be integrated. As for the dynamic analysis of mooring lines, the lumped mass

method (Fig. 4) and the slender rod theory (Fig. 5) are commonly used. The lumped mass method is equivalent to simulating the slender structure into a series of lumped mass node systems connected by springs (Kato 1982). The finite difference method is used to solve the dynamic problem, which can simplify the analysis of the structure without losing accuracy. It has been widely used. The slender rod theory applies the overall coordinates and slope and establishes the

Catenary Mooring, Fig. 4 The lumped mass method. (Image by MIT OpenCourseWare)

Catenary Mooring, Fig. 5 The slender rod theory

governing equations of the mooring line under tensile deformation and bending deformation (Webster et al. 2012; Ma et al. 2015). The finite element method is used to solve the dynamic problem. Its main advantage is that the nonlinear governing equations can be performed in the global coordinate system without coordinate system transformation. In comparison of the two methods, the equation computational speed of the former is faster, but the accuracy is smaller than the latter.

Composition Materials

The abovementioned mooring line can be composed of a single component material or a combination of multiple components on the basis of different needs. The most common product used for mooring lines is chain which is available in different diameters and grades. Although the steel chain is resistant to abrasion and is not easily damaged, the quality is high and the cost is high. Since the deep water mooring system has strict weight restrictions, the full chain system is generally not used. When compared to chain, wire rope has a lower weight than chain, for the same breaking load and a higher elasticity. The most common combination method is three components: top chain + steel cable + bottom chain. The use of multicomponent mooring lines needs to focus on the length and diameter of each component and the choice of buoys or weights. In this way, the top and bottom chains prevent damage to the top mooring line from long-term friction of the fairlead and subsea portion as well as undulating collisions (Smith and Macfarlane 2001).

Selection of Anchors

The restoring force of the catenary mooring line is mainly caused by its own weight. The bottom of the mooring line usually has sufficient length to contact the sea floor even if the floating structure system is in the worst sea conditions. Therefore, the seabed anchor is only subjected to horizontal forces and does not bear vertical forces (Fig. 2).

Catenary Mooring, Fig. 6 Drag embedment anchor. (From anchor manual 2005)

Drag embedment anchors (Fig. 6) are then employed to resist the horizontal loads, but not for large vertical loads; this is the most popular type of anchoring point available today. The drag embedment anchor has been designed to penetrate into the seabed, either partly or fully, and its holding capacity is generated by the resistance of the soil in front of the anchor (Ruinen and Degenkamp 2001).

Development and Challenges

In general, the traditional catenary mooring positioning system occupies an important position in the mooring positioning system of the mobile platform. However, the influencing factors to be considered in deep-water mooring systems are more complicated than those in shallow water, and their research needs more attention and consideration. On the one hand, the traditional steel anchor chain and wire rope system, with the increase of water depth, its self-weight increases, and horizontal stiffness decreases sharply, while the weight increase leads to the increase of the cost, and it will also cause the multifaceted impact about deployment and recovery of the mooring system. On the other hand, the new concept and new materials for the deep-water mooring system are continuously developed. For example,

polyester ropes with light weight and high strength and weight ratio have replaced steel cables in some cases. The application of the new material can not only reduce the weight of the mooring system, but also its mechanical properties are improved to suit deep water. The lightweight catenary mooring system developed in recent years overcomes many shortcomings of the traditional catenary mooring system in deep sea mooring, but neither the lightweight catenary line nor the traditional can't overcome the excessive deviation of the horizontal level under sea conditions; the greater the water depth, the more obvious this shortcoming. In addition, the use of such mooring systems in deep water requires a large number of mooring lines of larger diameter, which can take up a lot of space on the installation vessel. There are many problems that need to be solved, and the effectiveness and economy of the multiple component systems also need further study.

Introduction

The central monitoring system in underwater mining system is designed based on the OLE for process control (OPC) and the Ethernet technologies. The purpose of central monitoring system is to obtain promising performance on monitoring and controlling of all the related subsystems of the entire underwater mining system. In addition, the collaborative control subsystem (CCS) is also an important part of the central monitoring system.

Central Monitoring System

The concept of central monitoring system is the system which can obtain the monitoring and control of all the related subsystems, as well as all the parameters within each subsystem. The central monitoring system is a necessary part in the deep sea mining (Kirkham et al. 2020; Cormier and Lonsdale 2020; Hein et al. 2013; Wedding et al. 2015).

For ensuring the realization of ocean mining process, all the related subsystems, equipment and devices need to be monitored in real-time. That is to say, the central monitoring system is designed for monitoring and controlling all the related subsystems. The central monitoring system is composed of application layer, network layer, and device layer. It uses “OPC + Ethernet” mode to realize the communication connection between the upper computer and related subsystems, and then controls the main equipment of each subsystem to complete the relevant actions according to the instructions of the upper computer, and can realize the real-time monitoring and display of the main operating parameters of each subsystem.

Development of Central Monitoring System

In recent decades, the central monitoring system has developed from a single machine and functional control system to a multifunctional intelligent decision-making system. Generally speaking, the development of platform management system has experienced three stages (Han et al. 2004; Li et al. 2002).

First, the distributed control system with single function was applied before the 1970s. The sensors of the devices were directly connected with the controller or computer, which were directly controlled with simple function.

In the second stage, from the 1970s to the mid-1980s, the fieldbus system and supervisory control and data acquisition (SCADA) system have appeared, and the control system based on fieldbus network has been fully developed.

From the mid-1980s to now, with the development of computer, communication, and control technologies, the demand for comprehensive control of various functional subsystems is more and more obvious, and the technology is becoming more and more mature. Therefore the integrated platform management system emerges as the times require. At present, the integrated platform management system in developed countries has developed from a basic ship monitoring function system to an intelligent control system with large amount of information processing, fast processing speed, and complex decision support.

From the point of view of technical implementation, the traditional platform control system lays functional subsystem cable independently and collects the data by different functional systems. There are many cables in the system, and the wiring is very complex. The binding of control and human-computer interaction makes the console a special one.

The central monitoring and platform management system collects data nearby, which greatly reduces the number of system cables and makes wiring simple. The separation of control system and human-computer interface makes the console become a general one, reduces the number of spare parts, and makes the system secure and reliable. The shared information resources of the whole ship can realize complex closed-loop control and decision-making with high degree of automation. And the flexible control mode of central monitoring and platform management system reduces the staffing and the lifecycle maintenance cost.

Centralized Central Monitoring System

In the early application, the subsystems were discrete units and just simply connected. This kind of structure is also a solidified structure, lacking the ability of self-change and adapting to new products. Generally, the centralized structure has only one master node for information processing, and a master computer is used to complete all information processing and decision control.

The advantage of centralized structure is that only a few computers are needed, and each control module can access the global database. Because the master node grasps the global information and knowledge, the master node using certain intelligent technology may make the optimal system operation decision, and may be the global optimal decision. However, the key to the above advantages is that the scale of the system needs to be relatively simple and stable. For the system with complex structure and function, the speed of centralized processing of all information by the master computer may become a bottleneck that seriously affects the real-time performance of the system, so it cannot meet the requirements of resource scheduling and control for large complex

systems. One of the inherent defects of centralized structure is that once the main control node fails, the whole system will face the risk of collapse. In addition, the disadvantages of centralized control architecture include low fault tolerance, poor scalability, and long development cycle. However, some advantages of centralized control structure are still irreplaceable. In some small systems, this structure is very effective for global stability control, so that it is still applied in some cases. For example, Comau in Italy developed a set of software based on centralized control structure, which is used to deal with all control problems of flexible manufacturing system.

OLE for Process Control

OLE for process control is a set of standards pertaining to automated manufacturing process systems which facilitates industry-wide ease of communication between system controllers and plant equipment. The OLE identifier stands for Object Linking and Embedding, and the whole term is generally shortened to Object Linking and Embedding for Process Control, or OPC (Janke 1999; Li et al. 2005). The standards are of relevance to manufacturing processes based on the Microsoft Windows Operating System (OS) and are governed by the OPC Foundation. OLE for process control was developed in 1996 in an attempt to create a standardized set of process communication protocols based on the Microsoft Corporation's OLE, DCOM, and COM technologies for their Windows OS. The enforcement of the OLE for process control standards system allows ease of integration of automated manufacturing systems in a wide range of industries.

The OLE for process control system, or OPC, as it is more commonly known, has at its core a set of common objects, protocols, and interfaces. Together, these form a standardized communications bridge that ensures that control and execution systems can be moved about or added to a process seamlessly. As technologies in manufacturing and industry advance, so the OPC standards are upgraded and amended accordingly. The management of this process is handled by a group known as the OPC Foundation, which is responsible for its maintenance and implementation.

Prior to the advent of the OLE for process control system, a dedicated application had to be written for each new automated process. This was obviously time-consuming and expensive, and created an environment where industry players and machinery manufacturers could not develop or implement common systems. This led to systems being developed in isolation with commensurate losses in streamlining and efficiency. The introduction of the OLE for process control standards can, thus, be seen as one of the most significant developments in the history of automated process control.

Ethernet

Ethernet is a standard communications protocol embedded in software and hardware devices, intended for building a local area network (LAN). It was designed by Bob Metcalfe in 1973, and through the efforts of Digital, Intel, and Xerox (for which Metcalfe worked), “DIX” Ethernet became the standard model for LANs worldwide. The router with ethernet jacks is shown as Fig. 1.

A network interface card (NIC) is installed in each computer and is assigned a unique address. An Ethernet cable runs from each NIC to the central switch or hub. The switch or hub will act as a relay (though they have significant differences in how they handle network traffic), receiving and directing packets of data across the LAN. This type of networking, therefore, creates a communications system that allows the sharing of data and resources, including printers, fax machines, and scanners.

These networks can also be wireless. Rather than using a cable to connect the computers, wireless NICs use radio waves for two-way communication with a wireless switch or hub. In lieu of

Ethernet ports, wireless NICs, switches, and hubs each feature a small antenna. Wireless networks can be more flexible to use, but also require extra care in configuring security.

Ethernet and OPC-Based Central Monitoring System

The development of central monitoring system is based on the object linking and embedding for process control (OPC) and Ethernet technologies, that is, all the monitored subsystems, equipment, and devices are regarded as the OPC servers, and all these objects are communicating based on the Ethernet. The schematic of the OPC/ Ethernet based subsystem is illustrated as the Fig. 2. The detailed structure of the system is shown in Fig. 3.

Collaborative Control

Collaborative control system (CCS), also known as distributed control, is characterized by the fact that there is no master-slave relationship between entities in the system. They coordinate through mutual communication to achieve the goal of the system. The form of collaborative control is common in nature. To ensure the operation of ocean mining system, the collaborative control system is also of great importance. That is because the underwater environment is always very complex and unpredictable. So the descending and lifting processes of the mining vehicle are very complex. This will cause serious consequence for the entire ocean mining system. The collaborative control system obtains the relevant monitoring parameters from the central monitoring system in real time, and transmits the upper computer control instructions to the controlled equipment of A-frame system to control it to complete the relevant actions according to the control instructions. In addition, the collaborative control system has

Central Monitoring System, Fig. 1 Router with ethernet jacks

Central Monitoring System, Fig. 2 Schematic of OPC/Ethernet-based monitoring system

Central Monitoring System, Fig. 3 Detailed structure of OPC/Ethernet-based monitoring system

the function of emergency response, which should be able to realize emergency braking of the main equipment in case of communication failure.

Human Machine Interface

Human-machine interface, also called user interface or human-computer interface, means by

which humans and computers communicate with each other. The human-machine interface includes the hardware and software that are used to translate user (i.e., human) input into commands and to present results to the user.

The human machine interface (HMI) of ocean mining central monitoring system is designed in

detail in this section. The developing environmental is KINGVIEW v7.5. Some main HMIs are listed as Fig. 4.

As shown in Fig. 4, the main operation parameters of all the subsystems, equipment, and devices can be collected and communicated

Central Monitoring System, Fig. 4 (continued)

Central Monitoring System, Fig. 4 HMI of ocean mining central monitoring system based on KINGVIEW v7.5. (a) Login HMI. (b) Main HMI. (c) Monitoring HMI. (d) Mining vehicle control HMI. (e) Lifting pump monitoring HMI. (f) Intermediate cabin monitoring HMI

through the OPC/Ethernet mode. For example, in the main HMI shown in Fig. 4b, the operation mode can be shifted using the button above the HMI. In the monitoring mode, the operation parameters of all the related subsystems can be displayed within each window. However, in the control mode, the control parameters like the lifting speed of mining vehicle, the lifting mode of mining vehicle, and so on, can be set using the corresponding windows. In addition, the alarm function is also integrated into the system. That is to say, when the operation parameters are greater than the upper bound or less than the lower bound, the system will warn the operator to check and eliminate the fault.

Definition

In petroleum and natural gas extraction, a Christmas tree, or “tree,” is an assembly of valves, casing spools, and fittings used to regulate the flow of pipes in an oil well, gas well, water injection well, water disposal well, gas injection well, condensate well, and other types of wells. A tree provides numerous additional functions including chemical injection points, well intervention means, pressure relief means, monitoring points (such as pressure, temperature, corrosion, erosion, sand detection, flow rate, flow composition, valve and choke position feedback), and connection points for devices such as down hole pressure and temperature transducers (DHPT). ([http://en.volupedia.org/wiki/Christmas_tree_\(oil_well\)](http://en.volupedia.org/wiki/Christmas_tree_(oil_well))).

Background

The subsea tree and wellheads act as important roles in underwater production system. The subsea wellhead system has the same general functions with a usual surface wellhead, which seals and supports casing strings, and simultaneously, the subsea tree after completion and BOP (blowout preventer) stack during drilling are both supported with it.

A Christmas tree system is mainly composed with a group of valves located on an underwater wellhead for providing an effective interface between the underwater production system and well, as shown in Fig. 1. It is also called an X-tree, cross tree, or subsea tree. Christmas tree includes various valves applied to servicing, regulating, testing, or choking the stream of produced gas, oil, and liquid spilling over from the well below.

Christmas tree has various types, which can be applied to water/gas injection or underwater

production. Components of Christmas tree can be different in term of field developments and different projects.

Christmas tree is usually designed mainly according to the codes and API standard below:

- API 6A, Specification for Wellhead and Christmas Tree Equipment
- API RP 17A, Design and Operation of Subsea Production Systems
- API 17D, Design and Operation of Subsea Production Systems
- API RP 17G, Design and Operation of Completion/Workover Risers
- API RP 17H, Remotely Operated Vehicle Interfaces on Subsea Production Systems
- API 5L, Specification for Line Pipe
- DNV RP B401, Cathodic Protection Design
- ASME B31.3, Process Piping
- ASME B31.8, Gas Transmission and Distribution Piping Systems
- ASME BPVC VIII, Rules for Construction of Pressure Vessels
- AWS D1.1, Structural Steel Welding Code
- NACE MR-0175, Petroleum and Natural Gas Industries

Christmas Tree, Fig. 1 The structure of subsea tree

Dry Tree and Wet Tree System

According to the structure form, there are two types of Christmas tree are used in deep-water fields: dry tree and wet tree systems, which are illustrated in Fig. 2.

For the dry tree system, tree is close to or installed on the platform, nevertheless, wet tree can be anywhere in a field referring to tie-back method, cluster, and template. Dry tree platform has a central well bay for the surface tree, supplying convenient access to the wells for recovery and workover. Spars and TLPs (tension leg platforms) are usually used in a dry tree system.

The size of the central well bay of dry tree system is depended on spacing and well count, which is placed around by topside equipment. The surface tree is projected for full reservoir shut-down pressures. A large subsea manifold is

Dry Tree System

Wet Tree System

Christmas Tree, Fig. 2 Dry tree and wet tree system (Yong Bai and Qiang Bai 2019)

required to install on deck, and a skiddable rig is required for individual well interventions.

For wet tree system, trees and other related parts are exposed to the seabed environment. In deep-water field, for well completions, the wet tree system usually uses remotely controlled Christmas tree installation tools, but in shallow water, divers can deal with installation and operation. The wet tree platform has a central “moon-pool” for the installation of Christmas tree and marine riser. If its size is suitable, the wet tree system also can install other equipment, such as the BOP and subsea manifold. Wet tree system is suitable for widespread reservoir structures. They provide field expansion flexibility and a degree of vessel with simplified riser interfaces, but at a high cost of drilling and workover.

In recent years, operators have to reassess their strategies of rapid expansion in ultra-deepwater areas due to the technical difficulty and commercial competitiveness between dry tree and wet tree system. Globally, more than 70% of the wells in deepwater projects that are wet tree system. The data shows the industry’s confidence in the wet tree system.

Compared with wet tree system, the dry tree system requires a motion-optimized hull to adapt

the riser system. They are deemed to be limited in development flexibility and depth. Globally, most underwater oil field developments employing wet tree system. The dry tree system is not adapted to deep-water and ultra-deepwater situation in spite of widespread development in shallow to medium depth.

Systems Selection

In the design process, an objective and thorough assessment of dry and wet tree system option should be considered, including cost, risk, and flexibility, to ensure that the development concept that best matches the reservoir characteristics is selected.

The problem that operators often face is commercial metric, such as NPV (net present value) and capital cost, which are inconclusive. In the basic case of development examined, the commercial metric is displayed to generally prefer the wet tree system over the life cycle of the system, but the advantage to the dry tree system is not obvious. In this case, the operator must thoroughly evaluate the other significant different factors before making the final selection.

Through experience and technical analysis, the optimal Christmas tree system matching reservoir characteristics can be selected. The following are the basic selection points:

- Extrinsic factor: These factors are in the form of operator preferences, innovative thinking, project risk, project management, and people (each person's evaluation method may be different).
- Economic factor: Estimated net present value, IRR (Internal Rate of Return), project schedule, project cash flow, and possibly EPCI (Enhanced Proliferation Control Initiative) proposals (if any options are available at the time of selection) will undoubtedly be the key drivers of this choice.
- Technical factor: These factors are driven primarily by reservoir depletion plans and means, operating philosophy, concept maturity, field worldwide location and feasibility, reliability, and industry readiness.

[OCTM – Ore Collecting Test Machine](#)

Definition

Collector: Collecting attached ore or broken ore particles from the seabed.

Crusher: Crushing the collected ore or cutting the ore from the surface of the sea bottom to a specified size.

Introduction

In the process of seabed mining, the collector and crusher of the deep-sea mining vehicle is responsible for correspondingly collecting and crushing the ore covered in the seabed. The process and technology of deep-sea mineral resources collection and crushing mainly depend on the occurrence state of mineral resources in the seabed and the characteristics of seabed topography and geomorphology. It is easy to be collected for the

polymetallic nodules on the surface of sediments. Usually, the polymetallic nodules are first collected to the mining vehicle and then broken to required particles by crusher in the mining vehicle. Up to now, there are three representative methods that have been used in deep sea experiments, including mechanical-type collection, hydraulic-type collection, and mechanical-hydraulic-type hybrid collection. The conventional single toothed roller crusher is used to crush the polymetallic nodule. For the polymetallic sulfides and cobalt-rich crusts consolidated in the hard bedrock, the ore body shall be first excavated and stripped from the bedrock and then collected to the mining vehicle. In general, the ore body shall be broken to a certain particle size in the excavating process. As of this date, the representative methods that have been applied to the deep sea test mainly include mechanical mining crushing and hydraulic collection.

Collector and Crusher of Seabed Polymetallic Nodules

Polymetallic nodules occurred on the surface of seabed sediments with the depth of 4000–6000 m in Pacific Ocean are usually in a semi buried state (Kaufman 1980). Most of polymetallic nodules are spherical or ellipsoidal with a particle size of 2–10 cm and a density of about 2100 kg/m³.

It needs a certain degree of stripping force for the collection to strip the polymetallic nodules from seabed sediments. According to the measurement, the stripping force from the sediment with a shear strength of 3 and 6 kPa is, respectively, 25 N and 32 N for a nodule with the weight of 0.14 kg and the diameter of 6.4 cm. While the maximum force per unit area is 0.02 MPa when the total burial depth is doubled. Considering the insurance factor of 1.5 times, the stripping pressure is 0.03 MPa in the design (Wang 2015).

Collection Technology of Seabed Polymetallic Nodules

Up to now, hundreds of collection principles and institutional patents are invented, but only

mechanical collection principle, hydraulic collection principle, and hydraulic-mechanical combination collection principle are valuable in economy and technology.

Mechanical Collection Technology

Mechanical devices are used to collect the polymetallic nodules in the mechanical type, which is originated from agricultural potato harvesting devices. The principle and structure are relatively mature and efficient. However, the mechanism of the mechanical collector is complex, and its digging teeth are easy to be damaged result in blockage, and it is difficult to unload quickly.

In addition, the mining resistance of the collector is large to increase the walking load of the seabed mining vehicle. A mechanical nodule collector invented by Ocean Minerals Company (OMCO) is shown in Fig. 1. The nodule is excavated from the seabed and transported to the seabed mining vehicle by means of the rotary chain-tooth collector (Welling 1981).

Hydraulic Collection Technology

The hydraulic collection technology is researched and developed to separate and move the nodules on the surface of seabed sediments with water flow. Three main types of hydraulic collection are developed that are jet hydraulic collection, suction hydraulic collection, and lifting type. The principle of water jet hydraulic collection is typically based on the wall attached nozzle effect of the water jet. Under the negative pressure generated by the low-pressure water jet of the flat wall attached nozzle, the nodule is loosened from the sea floor and the surrounding seawater is pumped simultaneously, the nodule is lifted and transported to the inclined conveying pipe. The hydraulic suction collection uses the pump to produce suction in the pipeline, sucks the sediment around the pipe orifice and the nodule together, and lifts to a certain height. The principle of hydraulic lifting collection is that two rows of water jets are used from the front and back inclined to the seabed nozzle at a certain height from the bottom to wash and lift the nodule, and then the nodule are input into the

Collector and Crusher, Fig. 1 Mechanical collection technology (Welling 1981)

Collector and Crusher, Fig. 2 Hydraulic collector of nodule used in sea pilot mining system test hold by OMI (Brockett 1999)

transmission pipeline. This collection type was proposed by Berlin Institute of underwater engineering in Germany.

Figure 2 is the schematic diagram of the hydraulic nodule collection device used in Ocean Management, Inc. (OMI) seabed mining

Collector and Crusher,

Fig. 3 Hydraulic collector of nodule used in Chinese lake test mining vehicle (Liu and Yang 1999)

system test. Its working principle is to use high-pressure water jet to blow the nodule from the seabed and collect it on the seabed mining vehicle by using water flow (Brockett 1999).

The collector is a hydraulic collection mechanism with double row of nozzles for washing and mining and negative pressure conveying of the wall attached nozzles of the 1000 m class lake test polymetallic nodule mining vehicle. The schematic diagram is shown in Fig. 3 (Liu and Yang 1999). Structurally, two rows of nozzles are arranged inclined to the sea bottom at a certain height from the sea bottom. Firstly, the water jet is generated by nozzles to flush the nodule out of the sedimentary layer. Secondly, the jet washes off part of the sediment and lifts the nodule under the action of the formed rising water flow. Thirdly, the lifted nodules are sent to the crusher feed port under the action of the forward movement of the ore collecting device and the negative pressure generated by the nozzle attached to the wall.

Hydro-Mechanical-Type Collection Technology

Hydro-mechanical-type collector combining the double-row nozzle blanking mechanism with the gear chain conveying mechanism is to avoid the disadvantages of mechanical tooth digging and high energy consumption.

The working principle diagram of hydro-mechanical-type connector developed by Siegen University (Handschuh et al. 2001) is shown in Fig. 4. Hydraulic power is used to blow up the nodules, and mechanical chain-plate is used to

Collector and Crusher, Fig. 4 The working principle diagram of hydro-mechanical-type connector (Handschuh et al. 2001)

transport the nodules to the seabed mining vehicle.

Mechanical-hydraulic-type connector, which combines mechanical-type connector and hydraulic-type connector, has the advantages of low acquisition resistance, clean flushing and small power of tooth chain transmission, etc. However, it is difficult to determine the bottom height of the collector, hydraulic system parameters and channel shape, so it needs to be corrected through repeated tests.

In the series of sea trials carried out in the 1970s, the mechanical collection mechanism adopted by OMCO failed to continue for only 10 minutes due to the jam of the crusher. The hydraulic collection mechanism adopted by OMI

and Ocean Mining Associates (OMA), respectively, with the principle of water jet collection and the principle of suction and lift collection has a better effect, which has a higher collection efficiency than mechanical collection. Currently, the mining vehicles developed by China, Belgium, and South Korea all adopt hydraulic collection mechanism, and the test results show that they have achieved good results (McFarlane and Brockett 2008; Kim et al. 2019; GSR 2019).

These collecting devices can collect the nodule from the seabed to the mining vehicle. But for industrial application, a good design of nodule collecting mechanism should not only have high collection rate and low energy consumption, but also be able to minimize the disturbance of seabed sediment. Thus, the collecting device is required to minimize the damage to the seabed ecosystem and meet the requirements of the environmental protection regulations. Due to the lack of sufficient test and application verification, it is still a long way to obtain the most effective scheme for commercial application.

Crushing Technology of Seabed Polymetallic Nodules

According to the requirements of simple structure, light weight, and low crushing object strength (average compressive strength 5 MPa) (Wang 2015), it is more suitable to choose single toothed roller crusher. A typical crusher is shown in Fig. 5, with hydraulic overload jaw opening plate and linkage bottom door opening discharge mechanism.

Collector and Crusher of Seabed Polymetallic Sulfides

Seabed polymetallic sulfides originate from the mixing of hydrothermal fluid and cold sea water that erupts from the seabed, which is large in the seabed with the thickness of up to 10 meters or tens of meters. According to the mechanical properties of a large number of samples, the fracture characteristics of seabed polymetallic sulfides are similar to coal. Toughness and plasticity of seabed polymetallic sulfides are similar to salt and

Collector and Crusher, Fig. 5 Single tooth roller crusher used in China Lake test mining vehicle (Wang 2015)

potassium carbonate, and the axial compression strength of seabed polymetallic sulfides is less than 40 MPa.

Polymetallic sulfides deposit on the sea bottom surface can be collected easily by traditional mechanical or hydraulic machinery. In view of the distribution characteristics and the mechanical properties of polymetallic massive sulfide are similar to those of coal, the existing mature technology and equipment of land hard coal can be used for reference for its collection. Mechanical or other acoustic devices need be used to break the sulfide ore block and then collect it on the process flow.

According to the commercial mining system proposal of seabed polymetallic sulfide from Nautilus Minerals, the subsea operating device consists of three operating vehicles, namely, auxiliary miner (Fig. 6a), bulk miner (Fig. 6b), and gathering miner (Fig. 6c). The auxiliary miner opens up the mining belt, prepares the mining working face, and transports the excavated and broken ore grains to the vicinity of the mining vehicle. The bulk miner excavates and crushes ore bodies on the working surface. The gathering miner collects the ore grains excavated by bulk miner, and the ore grains cut by auxiliary miner, and then the gathered ore grains are pumped to the flexible hose by an underwater pump to the surface mining ship through riser (Nautilusminerals 2015).

Collector and Crusher, Fig. 6 Auxiliary miner (a), bulk miner (b), gathering miner (c), and cutter suction dredger cutter head (d) (Nautilusminerals 2015)

In view of the characteristics of polymetallic sulfide deposits in the waters of Okinawa, an ore collecting test machine (OCTM) was developed to verify the mining feasibility of polymetallic sulfides. OCTM adopts the integrated technology of crushing and collecting with the integrated mining head so as to reduce the mining time and the cost related to the auxiliary ship equipment and improve the productivity of offshore mining operations.

The spiral drum cutting technology and mechanism by mature coal mining on land is used for reference to cut and crush the polymetallic sulfide ore body in auxiliary miner, bulk miner, and OCTM. The collector of gathering miner and OCTM is based on the corresponding principles and schemes of river dredger and seabed Diamond miner, which is shown in Fig. 6d.

OCTM with two single-arm drum spacing reversing arrangement combining mining and collecting was developed through laboratory

principle tests and submarine collection head tests. A dredging head is arranged vertically in the center of the two drums. The dredging head is driven by slurry pump through the pipe. When it works, the cutting drum cuts the ore material, and the ore particles are collected in the center of the two cutting drums (Masuda et al. 2014). The schematic diagram of the mining head is shown in Fig. 6a and the mining head underwater operation diagram is shown in Fig. 7b. In 2017, the polymetallic sulfide mining test at a depth of 1600 meters was completed, and a total of 16 t polymetallic sulfide ore was collected (Ishiguro et al. 2013; Masuda et al. 2014; Okamoto et al. 2018).

Crusher of Seabed Cobalt-Rich Crusts

Cobalt-rich crusted deposits are mainly distributed on the slopes and top surfaces of seamounts, mid-ridge and platforms in depth of 400–4000 m,

Collector and Crusher, Fig. 7 Polymetallic sulfide mining head of ore collecting test machine (Okamoto et al. 2018)

attached to bedrock with crusts of 2–20 cm thickness. Their mechanical properties are similar to terrestrial hard coal. Regardless of the terrain, the coal cutter method can be used to peel and break the crust from the bedrock. However, the geological conditions for the occurrence of cobalt-rich crust deposits are extremely complicated. Some of the mining areas are relatively flat in the 2–3 km zone at the edge of the mountain, and most of the cobalt-rich crust mining areas are on slopes with slopes of 10–20 degrees (Qiu 2002; T. Yamazaki 2004). The micro-topography fluctuates greatly and the crust thickness is very thin with an average thickness of less than 10 cm. The key problem of collecting cobalt-rich crusts is how to remove the crusts effectively from the bedrock. The mining of cobalt-rich crust is limited by two key technologies. Firstly, the mining mechanism will fully excavate the crust ore body attached to the bedrock to ensure a high recovery rate. Secondly, the bedrock should not be cut off as much as possible to reduce the dilution rate. Generally, the recovery rate is generally higher than 80% and the dilution rate is lower than 25%.

According to the current information, the cobalt-rich crusts with commercial mining value are mostly in the form of thin-layer plate-like crusts covered by hard basalts and other types of hard bedrock. At present, researchers in the United States, Japan, Russia, and other countries have carried out the research on the principle

Collector and Crusher, Fig. 8 Cobalt-rich crust mining head (CIMR 2018)

scheme of the mechanical crushing and stripping method for cobalt-rich crusts, but there is no report on the in-depth design, manufacturing, and test work.

A seabed cobalt-rich crusts mining equipment for sampling test was developed in China. In the test equipment, the crusher is designed to be double arm single spiral drum from the successful experience of the spiral drum cutting technology of land mining, and the slurry pump is used as the collection mechanism according to the river dredging technology. When the equipment worked on the seabed, the spiral drum (as shown in Fig. 8) excavates the crust, and then the ore particles, crushed by spiral drum, are collected into the sampler by the slurry pump.

In September 2018, the mining sampling equipment was tested at the depth of 2019 meters in the cobalt-rich crusts contract area of COMRA. About 150 kg of crust particles were collected in four tests (CIMR 2018). The sampling equipment verifies the feasibility of collecting cobalt-rich crusts, and provides a self-adaptive collection method of cobalt-rich crusts. However, it is still necessary to solve the technical problem of efficient cutting, stripping, and acquisition of the crusts which are thin and crispy, distributed in hard bedrock.

[Ship dismantling](#); [Ship recycling](#); [Vessel dismantling](#); [Vessel recycling](#)

Definition

Nowadays, there are different ways of dismantling ships and offshore structures, i.e., complete dismantling and partial dismantling. For ship recycling, most the end-of-life vessels are usually sold to the international markets for complete

dismantling. It is a common way to export obsolete vessels to shipyards for recycling in both developed and developing countries as a way of resource recycling and reusing. However, some vessels, such as cargo ships and tankers, are partially dismantled and transformed into fishing farming, which would be beneficial to the environment. For offshore structure recycling, when an offshore field becomes unviable, the offshore infrastructures require decommissioning, by using one of the following alternatives – complete removal, partial removal, or remote reefing (Chandler et al. 2017).

Scientific Fundamentals

Historical Development

Currently, the core ship dismantling locations have been moved to developing countries, including India, Bangladesh, Turkey, Pakistan, and China (Mikelis 2008; Deshpande et al. 2012; Ormond 2012; Hiremath et al. 2015; Rahman and Mayer 2015; Du et al. 2017, 2018). However, the ship dismantling industry usually has severe negative implications on the environment, human safety, and health because of the hazardous materials and chemicals involved (Sonak et al. 2008; Neşer et al. 2008; Harris and Kahwa 2003). Recycling end-of-life vessels in an environmentally friendly manner is a major challenge faced by ship owners, shipbreaking yards, as well as government agencies worldwide (Du et al. 2018). Moreover, problems generated by the insufficiencies of current ship dismantling practices have consequences for not only the environment but also for occupational safety and the health of the workers.

Meanwhile, there are thousands of offshore oil and gas facilities and platforms all over the world, as well as subsea infrastructure, pipelines, wells, etc. Many of those offshore engineering infrastructure have been in service for several decades and are due or will soon be due to be decommissioned (Chandler et al. 2017). Typically, offshore structure decommissioning procedure includes the following steps – decommissioning planning and engineering, permitting and regulatory compliance, platform preparation, well plugging and abandonment,

conductor removal, mobilization and demobilization of derrick barges, platform removal, pipeline and power cable decommissioning, materials disposal, site clearance and verification, and post-job activities. Herein, this part aims to introduce complete and partial dismantling of ships and offshore structures that are end-of-life.

Complete Dismantling of Ships

The Sixth Meeting of the Conference of Parties to the Basel Convention in 2003 had adopted the Technical Guidelines for the Environmentally Sound Management of the Full and Partial Dismantling of Ships (hereafter as The Guidelines) as the technical guidelines for the hazardous wastes and their disposal during ship dismantling. The Guidelines had also been considered and adopted by IMO for IMO Guidelines on Ship Recycling in 2004. Meanwhile, the Hong Kong International Convention for the Safe and Environmentally Sound Recycling of Ships, 2009 (the Hong Kong Convention), also aims at ensuring the environment, safety, and health issues. These guidelines aim to enable ship dismantling facilities attain environmental sound management (ESM) by providing information and recommendations on procedures, processes, and practices for the countries during ship dismantling processes. Therefore, it is a major challenge to recycle end-of-life ships in both environmentally sound and safe manner ways.

As mentioned by the Basel Convention, ESM is defined as “taking all practicable steps to ensure that hazardous wastes or other wastes are managed in a manner which will protect human health and the environment against the adverse effects which may result from such wastes.” The Guidelines provide an overview of the elements to be considered for the complete dismantling of ships in order to achieve an environmentally sound ship dismantling, including preparations on the ship, ship dismantling facility, environmental management plan, etc. In this section, the procedures for different methods of ship dismantling are introduced and studied. The procedures include pre-demolition removal and preparations prior to ship dismantling operations, arrangement of ship dismantling facility, main works of ship dismantling operations, and the environmental management plan.

Environmental Management Plan

At the beginning of ship dismantling, an environmental management plan (EMP) is usually required to achieve the aim of environmental sound management for ship dismantling. The EMP includes the assessment of the potential environmental impacts during ship dismantling by conducting an environmental impact assessment, which helps to identify the environmental aspects and the environmental goals to be set for the facilities. The EMP, which is an all-encompassing document, covers all aspects of environmental issues at a macroscopic range, including the assessment of potential environmental impacts, the potential preventative measures, and environmental management system (hazardous materials management plan, contingency preparedness plan, monitoring plan, etc.).

Pre-demolition Removing and Preparations

Prior to ship dismantling operations, firstly, whatever method the yard uses to dismantle the ship, the ship should be fixed or moored well to minimize displacement of the ship. Thereafter, some preparatory procedures should be implemented on the ship, such as overall checking onboard, collecting related information, and planning of ship dismantling; deployment of access gangway and warning signs; open and free any gas; oxygen and explosion tests in sealed cabin; deployment of oil booms; emergency facilities equipment; etc. More details are shown in Table 1.

Ship Dismantling Facility Arrangement

It is very important to make sure that all of the dismantling facilities and equipment should be working properly and the dismantling yard should be cleaned and comprises certain key

Complete and Partial Dismantling, Table 1 Preparatory procedures before main work of ship dismantling

Item	Action	Purpose
Prepare inventory list of hazardous materials and polluting wastes	Make a detailed ship dismantling plan Identify, quantify, and locate different types of hazardous materials and wastes on board	To arrange the sequence and nature of the work to be executed and ensure human health and safety and ESM
Remove and clean the liquids, e.g., fuels, oils, etc.	Remove the hazardous materials, e.g., asbestos, Polychlorinated biphenyl (PCBs), tributyltin (TBT) paints, etc. Clear all the residual materials before cutting process Remove crew's furniture, storage, tools, and other sundries Pump out and drain off the oil in oil pipes, oil tanks, and lubricant systems, and clean the tanks Remove harmful and harmless insulation materials Remove other dangerous (toxic, flammable, and explosive) items such as dump oil, paints, high-pressure cylinder, etc.	To ensure that the ship is ready for dismantling in safe and clean conditions
Removal of equipment	Remove consumable and loose equipment Remove reusable components	To ensure that the cutting operations are more efficient
Securing	Deploy safe access to all areas, compartments, tanks, etc. ensuring breathable atmospheres Create safe working conditions for hot work, including cleaning/venting, removal of toxic or highly flammable paints from areas to be cut, and testing/monitoring before any hot work is performed Deploy emergency facilities equipment	To ensure that working procedures and operations are undertaken in a safe manner

Note: Adapted from the Basel Convention (2003)

functionalities. The equipment includes different kinds of cranes, forklift trucks, loaders, transport vehicles, cutting equipment, etc. Whichever method used for dismantling, the shipbreaking yard should include various zones for different purposes during dismantling. For an environmentally sound design of a yard, it is important to discern what activities take place in which zone, and what associated hazards are to be considered and prevented through environmentally friendly design. The zones shall comprise certain key functionalities, including containment for spills and leakages of hazardous materials/liquids, certain areas for dismantling blocks and sections into small pieces, specially equipped warehouse and appropriate containment for hazardous and toxic materials removal (such as asbestos), temporary regions for benign materials and hull blocks/sections, secure storage rooms/areas for hazardous wastes, certain regions for fully processed materials and equipment that can be reused and recycled, and proper disposal facilities for persistent organic pollutants.

Main Works of Ship Hull Dismantling

The main work of ship hull dismantling follows the pre-demolition removal and cleaning, and the layout of dismantling zones and facilities/equipment. Various techniques applied for ship dismantling have different costs and different degrees of environmental and social impacts. Currently, there are mainly four methods for ship dismantling. These include beaching, slipway or landing, alongside or pier breaking, and dry dock, as shown in Table 2.

During the first dismantling, the ship is usually broken down into blocks or sections. Piece cutting is needed to cut the blocks into pieces on site for secondary dismantling, especially for alongside or pier breaking method. The workers should clean up the residual oil and wastes on the blocks so that they can be disposed of separately. As a requirement, the blocks are cut into steel sheets, profiled materials, and waste steel and, respectively, placed in a certain place (Du et al. 2018). A procedure for dismantling a LNG (liquefied natural gas) vessel, which applies pier breaking method, can be seen in Fig. 1.

Complete Dismantling of Offshore Platforms

Offshore oil and gas platforms are aging gradually around the world. Those end-of-life offshore structures are decommissioned and removed by ways of complete dismantling and partial dismantling. For complete dismantling of offshore platform, the removal procedures include platform preparation and cleaning, conductor removal, removal of deck and equipment, complete removal of jacket or hull, site clearance, etc.

Platform Preparation

For platform preparation and cleaning, the main procedures are as follows.

- Prepare the facilities for removal.
- Shut down the facilities and equipment.
- Topside inspections.
- Underwater inspections, conducted by divers and remotely operated vehicles (ROVs).
- Plug and abandon the wells permanently, and abandon the pipelines.

When removing the topside of the platform, the following steps shall be carried out.

- Flush and clean the tanks, process equipment and pipes, and dispose of the residual hydrocarbons on the platform.
- Remove the equipment.
- Cut the pipes and cables.
- Divide the platform modules into individual units.
- Weld padeyes and remove obstructions for deck module lifting.
- Reinforce local structure for lifting.
- When removing the jacket, marine growth can be removed from the structure at sea if possible.

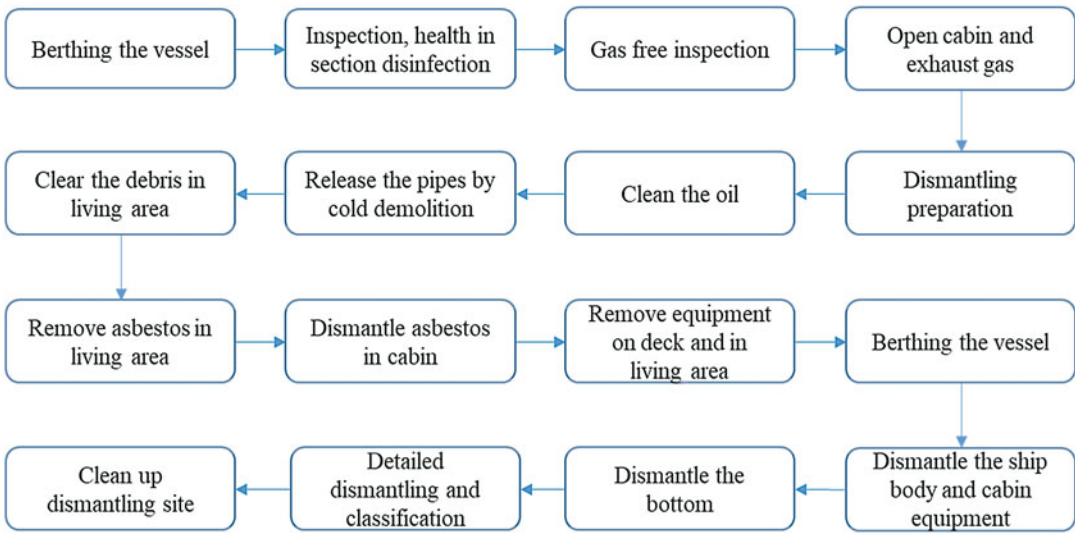

Conductor Removal

The conductors can be removed during platform decommissioning operations or prior to the arrival of heavy-lift vehicle. The conductors can be severed by using one of the following alternatives: explosive, abrasive cutting, mechanical cutting, and diamond wire cutting. When pulling the conductors, the following methods can be used:

Complete and Partial Dismantling, Table 2 Comparison of different ship dismantling methods

Ship dismantling method	Procedures	Advantages/disadvantages	Key locations
Beaching	The ship is driven to a tidal flat on a high magnitude tide and then pulled up the beach as far as possible The items and steel are removed from the ships by gas or oxygen cutting All operations take place directly on the beach in a relatively small and congested area The winches drag the steel pieces up the beach Large blocks may also be cut from the ship, released onto the mudflats, and dragged individually by the winches Once onshore, everything is cut into smaller pieces progressively and then taken from the yard by lorry or truck	Does not require investments in infrastructure or technology The moving cranes and motorized winches can be reused Labor-intensive Unsuitable for the use of heavy lifting gear Not allow for containment of hazardous substances Any spills of oil or cargo remaining would be swept out to sea and cause environmental issue	The regions with high tidal variation and wide mudflats Chittagong in Bangladesh Alang in India Gadani in Pakistan
Slipway or landing	A modification of beaching method essentially, with some crucial differences The ship is driven onto the shore or on a concrete slipway connecting shore and sea Ship sections are removed by a mobile crane working from the shore, and the ship is pulled onto the shore gradually Steel pieces are also removed from the ship by the mobile crane After the ship is lightened, it will be dragged up the shore for further dismantling A temporary quay or semipermanent jetty may also be added	Comparing to beaching method, this method is comparatively safe and environmentally friendly Any accidental spillages can be contained due to the lack of racing tides	Typically used in areas where the tidal flow is low and easily predictable Aliaga Turkey Some other EU Countries
Alongside or pier breaking	The ship is immobilized on a wharf or quay in a sheltered harbor or river The ship is secured alongside in the sheltered waters The superstructure is dismantled from top to bottom and from outside to inside The cutting usually follows the welding lines Usually uses cold dismantling method for oil pipes It is mandatory to drain the remaining oil, gas, and water inside the equipment and conduct gas-free check before cutting during engine room dismantling Dismantle the connection pipe and parts with the equipment at first Maintain the ship's balance at all times A crane removes the hull from the top to the bottom The last piece (such as the double bottom) may be lifted or sent to a dry dock for final cuttings	Results in pollution on alongside, which can be monitored and controlled It is a safety and environmental sound way	Usually applied in calm water China Myanmar Few places in Europe
Dry dock	The ship is driven to an enclosed, flooded dock, and the water is pumped out The ship is then dismantled piece by piece On completion, the dock is cleaned and flooded again for the next ship	With a minimum risk of environmental pollution The cost is the highest Rarely used presently due to its high cost	The USA and Europe practice this method Leave Sley International's facility in Liverpool, UK

Note: Adapted from Hossain (2017), Demaria (2010), and Du et al. (2018)

Complete and Partial Dismantling, Fig. 1 Ship recycling procedure for LNG (Du et al. 2018)

casing jack, drilling rig, platform crane, and the crane on heavy-lift vehicles.

Deck and Module Removal

The removal of topsides is in reverse sequence of the installation procedures. The modules shall be removed and placed on a cargo barge, which is fixed on the cargo barge by welding. The deck and module removal can also be carried by floatover method, which requires a specially designed vessel that can be partially submerged by ballasting and raised by deballasting. The cargo barge is then sent to the onshore disposal yard.

Complete Removal of Jacket and Hull

Complete removal of jacket can be conducted by separating the structure from its foundation and transporting it in whole or in pieces to onshore yard for further dismantling. Explosive method is usually to separate the structure from its foundation. Prior to the explosive detonation, certain surveys need to be carried out to ensure that the marine mammals are not near the platform. Usually, explosives are placed in the main piles and skirt piles at least 15 ft below the mudline. If the lifting capacity of the heavy-lift vehicle is insufficient, buoyant can be added to the served jacket to reduce

the weight. Large jacket can be towed to shallower water at first, then cut to sections, and sent to the onshore disposal yard.

After the complete removal of the platform, both the site and any location where the jacket is cut have to be cleared of debris and verified that they have been cleared. The site can be cleared by trawlers dragging nets across the bottom in a recorded grid pattern of specified dimensions or by the use of other authorized methods.

Partial Dismantling of Offshore Platforms

When offshore platforms require decommissioning, there are usually different ways, including complete removal, in situ decommissioning (leaving the infrastructure in place either completely intact or with the topsides removed and legs toppled), removal and relocation offshore platforms (for example, as a dive site or fishery), as well as partial removal (removing some parts of the infrastructure while leaving others in situ) (Ekins et al. 2005; Chandler et al. 2017). Partial dismantling usually happens in the decommissioning of offshore platforms. Platform jackets or hulls may be decommissioned using one of the following alternatives – complete removal, partial removal, or remote reefing. These alternatives vary only in the methods used

to remove the jacket or hull. For any given platform type, the platform removal preparation, well P&A, and pipeline decommissioning are the same for all removal alternatives.

The advantages and disadvantages for dealing with offshore platforms in different ways, i.e., leave in place, partial removal, and complete removal, are shown in Table 3.

Complete and Partial Dismantling, Table 3 Advantages and disadvantages for different methods of platform removal

Option	Advantages	Disadvantages
Leave in place	- Poses no harm to marine life - Immediate cost savings - Provides recreational fishing, diving habitat - Provides emergency safe havens - Maintains status - Structure remains visible - Requires no research and development - Requires no site clearance - Provides migratory animal habitat (surface) - Provides reef habitat (subsurface) - Suitable for structures at water depth more than 400 feet	- Maintains unnatural habitat - Maintenance costs escalate with age - Requires protective coating above water - Requires cathodic protection under water - Requires navigation-aid lights and horns - Remains susceptible to storm damage - Continues conflicts with other users - Potential liabilities - Unauthorized boarding - Collisions - Surface and subsurface navigation hazards - May require eventual removal with - Reduced structural integrity - Increased safety risk - Increased cost - Negatively affects construction/removal industry - No recycling of steel - Requires changes in regulations and laws - Not suitable for structures at water depth less than 400 feet
Partial removal	- Potentially reduces harm to marine life during removal and maintains some reef habitat - Potentially cost effective - Requires no maintenance - Requires no site clearance - May provide recreational fishing and diving habitat - Operators released from liability - Encourages innovative removal methods	- Does not return habitat to natural state - Eliminates habitat structure in upper range of water column - Must maintain buoys - Useful only in water depths allowing sufficient clearance - Potentially increases diver risk during removal - Decreases shrimping access - Liability attaches to regulatory agency - Court test inevitable - Creates navigational hazards (surface and subsurface) - Loss of resources - Eliminates surface habitat - No recycling of steel
Complete removal (at 15 feet below mudline)	- Meets shrimper requirements - Maintains clearance for trawlers - Requires no changes in regulations or laws - Poses no navigational hazards - Eliminates liability and site maintenance - Allows reuse and recycling	- Environmental impacts - Relocates or eliminates reef habitat - Fish kill from explosives - Expensive to operators - Explosives require an observer program - Restricts use of explosives - Discourages development of nonexplosive techniques - Requires transportation to shore or reef site - Requires site clearance - May require backfill - Hazardous to divers - Potential removal problems from soil skin friction at 15 feet below mudline

(continued)

Complete and Partial Dismantling, Table 3 (continued)

Option	Advantages	Disadvantages
Complete removal (at 5 feet below mudline or less)	Immediate cost savings Requires less jetting Minimizes problems from soil skin friction Encourages use of nonexplosive methods Less hazardous to divers Easier to clean for access by mechanical or abrasive tools Meets shrimpers requirements Nothing remains above mud line Reuse or recycling possible Poses no navigational hazards Requires no backfill Eliminates liability and site maintenance	Requires changes in regulations and laws Explosives may still be necessary in some cases although advanced techniques using smaller charges could be used Site clearance required Environmental impact Relocates or eliminates reef habitat Requires disposal

Closing Remarks

Different from partial dismantling of offshore platforms (such as offshore jacket platform), generally, the ships are completely dismantled in different ways after a life span of around 30 years. Specifically, the environmental management plan for ship dismantling, pre-demolition removing and preparations before ship dismantling operations, ship dismantling facility arrangement, and the dismantling procedures for different methods of ship recycling have been introduced in this paper. The end-of-life ships usually contain many kinds of hazardous materials which may result in health, safety, and environmental issues if they are not disposed properly. Therefore, an environmental management plan is needed; advanced techniques remain to be developed to enhance the prevention and protection of the environment, human health, and safety. The steps for the complete dismantling of offshore platforms have also been discussed. “Design for recycling” concepts are meaningful ways of improving the health, safety, and environmental conditions during ship dismantling.

Compliant Tower Platform

Junfeng Liu

Shanghai Jiao Tong University, Shanghai, China

Synonyms

Single anchor leg mooring (SALM); Single point mooring (SPM)

Definition

A *compliant tower (CT)* is a fixed rig structure normally used for the offshore production of oil or gas. The rig consists of narrow, *flexible (compliant) towers* and a piled foundation supporting a conventional deck for drilling and production operations. *Compliant towers* are designed to sustain significant lateral deflections and forces and are typically used in water depths ranging from 1,500 to 3,000 ft. (450–900 m). At present the deepest is the *Chevron Petronius tower* in waters 623 m deep (https://en.wikipedia.org/wiki/Compliant_Tower).

Basic Characteristics of Compliant Tower Platform

The compliant tower platform consists of the tower shaft, buoyancy chambers, ballast

Compliant Tower Platform, Fig. 1 A compliant tower platform diagram (Benaroya and Gabbai 2008)

chambers, the deck, and the base, as shown in Fig. 1. The shaft is connected to the seafloor through a universal joint. The base can be either piled or gravity type. The compliant tower platform is among the first elaborate compliant design to be used in the ocean service. “It serves as the first link between the sea-keeping analysis of the free body, traditionally the domain of the naval architect, and the environmental load analysis of the permanent structure, the traditional task of the ocean engineering” (Young 1983). The extension of the concept of single leg compliant tower platform has led to the development of the multi-hinged compliant towers (see Fig. 2). In the design of the multi-hinged compliant towers, there are several columns which are parallel to each other. The columns connect the deck and the foundations. The universal joints ensure that the columns are always parallel to each other, and the deck is always in horizontal position. This type of multi-hinged compliant tower can be used at large water depth.

The compliant tower platform is suitable for seawaters between 60 and 200 m. Also, shafts can be series connected, which could allow larger water depth. In 1977, the single anchor leg mooring (SALM) with multi-hinged articulated tower in the Thistle field in the North Sea was installed at the water depth

Compliant Tower Platform, Fig. 2 A multi-hinged compliant tower platform diagram

of 174 m. The compliant tower platform can be used for single point mooring (SPM), loading terminals, control towers, and early or full production facilities. In some marginal fields where reserve size does not warrant large facilities, it may also be used as a production platform.

History of Compliant Tower Platform

In the year 1963, due to the needs of industries, the first compliant tower platform was designed. In 1968, the first full-scale compliant tower platform to be used for experimental purposes was built. This platform worked at a depth of 110 m. This platform existed for 3 years at the site, during which researchers carried out many tests demonstrating that the compliant tower platform can be used in offshore engineering. In 1977, Burns and O'Amorim proposed the design and construction of two compliant tower platforms (Burns and O'Amorim 1977). The two

compliant tower platforms worked at a depth of 140 m. The design took into account the dynamic response and the strength of the base under the wind, wave, and current loads. The main structures of these two compliant tower platforms include base, universal joint, ballast chambers, buoyancy chambers, and the shaft. In the year 1990, the world's largest SPM compliant tower platform was built in 1989 in the Timor Sea in the northwestern of Australia. This compliant tower platform can withstand waves up to 9 m, wind up to 47 m/s, and current up to 2 m/s.

Main Characteristics of Compliant Tower Platforms

The tower shaft is the main structural component and is hinged on the seabed. The tower shaft can be a tubular cylinder or a steel lattice column. There is normally buoyancy chamber near the water surface. At the bottom of the shaft, there is always a ballast chamber. The oil production system is set up on the deck. The buoyancy chamber near the water surface provides buoyancy, and the buoyancy forces ensure the compliant tower platform is in an upright position. The larger the buoyancy, the smaller the tower shaft's motion caused by the wave force.

Besides, the damping effects of compliant tower are of great importance for the dynamic response of the whole platform. The influence of frictional damping, structural damping, and viscous damping on the vibration response amplitude is different. Frictional damping has the greatest influence on the amplitude attenuation of free vibration response without wave force, followed by structural damping, while viscous damping of fluid is the least (Hao 2008). In other words, the control of frictional damping can well control the response of the platform and enable the platform to quickly return to the equilibrium position after being stressed.

In addition, the difference between the compliant tower platform and the traditional steel structure platform is that there is no pile inserted into the seabed in the compliant tower platform, while

the pile of the traditional steel structure needs to insert into the seabed to resist loads of various forces at sea. Therefore, it is more convenient to construct and install a compliant tower platform and cause little hazard to the seabed environment. The compliant tower platform relies on its own huge moment of buoyancy to adapt itself to the waves without affecting drilling and production operations. In the case of not using, the ballast water in the base can be drained, and the base drifts up a little. So the tower platform can be easily transported by tugboats.

Furthermore, because the compliant tower platform connects to the seabed, the capability to resist the seismic load deserves great attentions. Some researchers (Han et al. 2006) analyzed the natural vibration characteristics and the seismic response characteristics of the platform by establishing the nonlinear governing equations of the compliant tower platform under earthquake excitation. The influence of different depths and the friction coefficient of the bottom universal joint on the platform response were also discussed. It is found that the seismic load acts on the platform can cause vibration of the compliant tower platform; when only the average water depth is changed, while keeping other parameters unchanged, the seismic response decreases with the increase of water depth; and when the friction coefficient of the bottom universal joint is increased, the amplitude of the seismic response decreases, and increasing the friction coefficient properly can effectively reduce the seismic response of the compliant tower platform.

The compliant tower platform has its own advantages and disadvantages. Compared with the traditional steel structure platforms, this type of platform can save a lot of steel. Because of the small size of this type of platform, small wind and wave force, simple structure, and low cost, the compliant tower platform is an ideal platform for deep water. The natural frequency of this type of platform is much lower than the wave frequencies. A salient feature of this type of platform is that the buoyancy chamber is near the sea surface, so the wave load is principally caused by inertia.

Although compliant tower platform has quite a lot of advantages, there are also some

disadvantages. The disadvantage of this platform is that due to practical and economic reasons, the buoyancy of the compliant tower platform is not enough, and the platform may swing too large in some cases. Sometimes the base may slide along the seabed. Besides, in severe sea state, the motion of the compliant tower platform can be too large to work normally.

Computational Fluid Dynamics in AUV/ROV/HOV Hydrodynamics

Zhe Jiang and Pengfei Sun
Shanghai Engineering Research Center of Hadal Science and Technology, Shanghai Ocean University, Shanghai, China

Definition

Hydrodynamic performance is one of the most important performances of AUV/ROV/HOV; the

economy, practicability, and safety of submersible can be affected directly by its advantages and disadvantages. Computational fluid dynamics (CFD) is an important method to research the hydrodynamic performance of submersible. It is a systematic analysis of physical phenomena including fluid flow through computer numerical computation and image display. The flow can be numerical simulated by the CFD under the control of the basic equation of the flow. The distribution of physical quantities at various positions in the flow field of extremely complex problems and the changes of these physical quantities with time can be obtained through the numerical simulation. The flow field of submersible can be obtained in CFD results, laying a good foundation for the further optimization of submersible designs.

Scientific Fundamentals

The Basic Concept of CFD

The fields of the continuous physical quantities in the spatial domain, such as velocity field and pressure field, are replaced by a series of sets of variable values at finite discrete points. Through a theoretical relation, the algebraic equations of the relation among the variables at these discrete points are established, and then, the approximate values of the variables are obtained by solving the algebraic equations (Renilson 2015).

The Basic Procedure of CFD

Actually, there is no standard CFD procedure. A general procedure can be expressed as below (Hu and Li 2015) (Fig. 1).

Characteristics of CFD Method

There are usually three methods to research the hydrodynamic performance of submersibles: theoretical formula calculation method, experimental design method, and CFD method. The theoretical formula calculation method can only be used for simple problems and qualitative analysis. Compared with the theoretical formula, the experimental method has the characteristics of strong authenticity and high reliability. However, due to

Computational Fluid Dynamics in AUV/ROV/HOV Hydrodynamics, Fig. 1 The flow chart

the constraints of site and environmental conditions, the experimental research is difficult to be widely used. Compared with the traditional theoretical and experimental methods, CFD method has the following characteristics (Wang 2013):

1. Advantages:

1. Strong adaptability to physical problems and wide range of application.
2. Not subject to conditions, with more flexibility.
3. The underwater flow field of the submersible can be visually displayed.

2. Disadvantages:

Compared with the other two methods, CFD method has the characteristics of unrestricted conditions and strong adaptability, but it also has a few limitations.

1. The CFD numerical solution is an approximate calculation method, which can only get the numerical solution of a finite number of discrete points, with certain calculation errors;

2. It involves a large number of numerical calculations and requires high computer configuration.

Key Applications

CFD Software Structure and Common Commercial Software

To solve different types of engineering problems, complex processes are integrated in CFD software, which basically include three steps: pre-processing, solution, and post-processing. The corresponding modules are preprocessor, solver, and postprocessor.

1. Preprocessor

The preprocessor is used to complete the work of preprocessing. In the preprocessing phase, the following tasks should be completed by engineers:

- Establish the geometric computational domain of the physical problem.
- The computational domain is meshed into nonoverlapping subregions.
- Select the control equation.
- Define the property parameters of the fluid.
- Set boundary conditions for geometric computational domain.
- Set the initial conditions for transient physical problems.

At present, preprocessing software which is currently used includes ANSYS ICEM CFD, Pointwise, Gridgen, Hypermesh, GridPro, etc. (Wang 2013).

2. The solver

The task of the solver is to read into the grid file (e.g., “.msh”), boundary conditions, control parameters, etc., by the preprocessor, and then, the results can be outputted and calculated according to the solution algorithm specified by the user. For the convenience of users, pre-processing functions are attached to some software solvers.

At present, CFD solution software which is commonly used includes ANSYS Fluent, ANSYS CFX, STAR CCM+, Phoenix, etc. (Wang 2013).

3. Postprocessor

The data obtained from the calculation is presented in an intuitive way through the post-processing, which is convenient for users to analyze and engineering application. The data is presented in some ways which includes:

- Data table: resistance, lift, moment, speed, and other physical quantities
- Curve diagram: reflect the changing rule of each physical quantity
- Nephogram: reflects the spatial distribution of physical quantities, such as pressure contour, velocity contour, vortex contour, etc.
- Vector diagram: reflect the vector spatial distribution, such as the velocity vector diagram
- Animation: reflect physical quantity changes with time in the form of animation

At present, the commonly used software of CFD postprocessor includes ANSYS CFD-POST, Tecplot, EnSight, ParaView, etc. (Wang 2013).

In addition to commercial software, users can also compile and modify the code to form their own computing software according to their requirement. Commonly used CFD open-source software (OSS) includes Open Foam, SU2, etc. (Wang 2013).

CFD Applications in Submersible Design

1. Prediction of submersible resistance and effective power

State-of-the-art CFD techniques can be used to estimate the resistance of an underwater vehicle, either deeply submerged or close to the surface. In the preliminary design stage of AUV/ROV/HOV, it is necessary to configure the system power unit. Therefore, resistance and effective power prediction are necessary. The advantage in CFD method is short calculation period and low cost. By simplifying the model of the designed submersible firstly and then simulating the flow field around the submersible with CFD method, the resistance of the submersible in different speeds can be obtained. Finally, the effective power of the designed submersible can be predicted through a certain processing of results. In order to

ensure the effectiveness of submersible numerical calculation, it is usually necessary to compare the calculated results with the experimental results.

2. Shape or molded lines optimization of AUV/ROV/HOV

The shape or molded lines optimization is more conducted for AUVs or HOVs rather than ROVs, since the power of ROVs is supplied from the surface ship through umbilical. However, AUVs or HOVs normally carry the battery themselves to navigate or perform certain operations under the sea. So for AUVs or HOVs, shape or molded lines optimization are usually conducted to achieve as small resistance as possible to better utilize energy. Since CFD can be used effectively to determine the effect of small changes in the hull form, it makes CFD a useful tool in the molded lines optimization.

3. Maneuverability analysis of submersible

During the design stage, it is necessary to research the ability and performance of the submersible when changing its motion direction and attitude through the control device. For the maneuverability analysis of submersible, it is necessary to establish six degrees of freedom equation in space to determine the external forces on the submersible (including gravity, buoyancy, thrust, and hydrodynamic force). Among them, the hydrodynamic force on the submersible is generally represented by the hydrodynamic coefficient. Therefore, the CFD method to calculate the hydrodynamic coefficient of submersible is the precondition to research the maneuverability.

Definition

Concept design is the first part of basic design, followed by preliminary design. It turns the mission requirements into the characteristics of the systems, developing two or more design alternatives from which a design is selected in accordance with specified criteria.

Scientific Fundamentals

Concept design is the first part of basic design, followed by preliminary design. In general,

according to E. E. Allmendinger (1990), it often involves the following stages:

1. Development of performance requirements, or system capabilities, from the mission requirements.
2. Determination of the principal characteristics of the systems required to achieve these capabilities, which enable new construction systems to be designed and existing systems to be selected and altered if necessary.
3. Estimation of capital and operating costs of the systems.
4. Identification of one or a few mission systems from among a series of alternatives which optimally meet performance requirements to the extent possible considering design constraints acting.

The system discussed here includes the total system which is also called the mission system and its supporting systems. The supporting systems provide the submersible with shore-based facilities, housing maintenance, repair and administrative activities, transportation, launching and retrieval services, navigation, and even with land-transport vehicles, air-transport vehicles, seafloor-based transponders, and submarines. The submersible itself and other systems should coordinate with each other in order to achieve the mission in the most effective manner. Therefore, it is important to consider the series of individual systems as a whole and take their interaction into account.

It is often convenient to describe a system as isolated from its environment by a boundary for the purpose of studying its internal behavior and interaction with its environment. A mission system is designed to serve one or more underwater missions. The boundary of the mission system encloses individual or systems, each enclosed by its own boundary, illuminating the fact that the mission is completed by a submersible supported by other systems.

Many mission systems are designed in the beginning with most of the potential systems already existing and some nonexistent. Existing systems require from no to extensive alterations to

convert them to systems, within equivalent amounts of design effort, construction, and costs involved. As for nonexistent systems, they must be designed and constructed “from scratch” and are expensive among all the systems.

Design Constraint

There are many design constraints imposed on the mission system and its individual systems. These constraints can be categorized into three kinds including mission external design constraints, mission internal design constraints, and design criteria.

Mission external design constraints (MEDC) come from outside and are external to the boundary of the mission system, which means that they are independent of all mission considerations. The sources of MEDCs may include environmental, technological, economical, legal, sociological, physiological, and psychological. Some of MEDCs cannot be changed by designers, for example, environmental factors like the speed of current and the height of wave cannot be determined by the engineers. Some of them, however, can be controlled by designers. For example, during the process of designing the hull, the material, one of the technological factors, can be selected by the designer. Once the material has been determined, the following stages will be constrained by its characteristic.

Some of sources of MEDC will change as time goes by. For instance, the technology or the policy of the law at the stage of construction may be different from which when being designing. Some of these changes will have a great impact on the procedure of design. Therefore, it will be better for a designer to take it into account.

Mission internal design constraints (MIDC) come from inside and are internal to the boundary of the mission system or any lower-level system. The sources of MIDC are the interaction between the systems that influence each other. Some constraints between two systems are weak, but some are strong.

Design criteria (DC) afford standards for judgments regarding design procedures and for selecting system components (Allmendinger

1990). The use of specific structural formulas and the requirements of critical system components based on state-of-the-art technology are examples. The examples of design criteria also include the basis for optimization, cost-effectiveness, or minimum weight. And these design criteria may be formulated by the owner, the designer, or the classification society.

Concept design turns the mission requirements into the characteristics of the systems. It includes feasibility studies and completion of the optimum designs. Feasibility studies are concerned with the development of those performance requirements and associated system characteristics, which have significant impact on the cost-effectiveness optimization process. Completion of the optimum design, however, involves developing other major performance requirements and characteristics which are essential in defining systems but do not have significant impact on the optimization process (Allmendinger 1990).

Feasibility studies produce a series of mission system alternatives, all of which meet the demand of mission requirements and are technically feasible. One or some of these alternatives will be chosen to be the input of preliminary design stage. The number of the alternatives depends on the complexity of the task and the implication of optimizing techniques. Each alternative is composed of a unique combination of systems, each of which has its unique capabilities, characteristics required to achieve these capabilities, and cost associated with providing these characteristics. Certain unique systems may appeal in more than one combination, but individual combinations are not duplicated in other alternatives. Combinations of systems that make up the mission system alternatives may vary in number, capability, and state, all of which are related to the functions required to fulfill the mission tasks, the time for accomplishing these tasks, and even the economic benefits.

Figure 1 shows a “feedback line” from concept design to the mission requirements which indicate that certain changes in performance requirements may lead to changes in certain mission requirements, a procedure which involves

communication between owner and designer. According to Fig. 1, there are two inputs to the “feedback line”: one from the existing line of the mission system alternative and another from the optimization process. At first, it will be recalled that all of these alternatives must meet performance requirements and be technically feasible from the availability and operability points of view. As a result, in forming these alternatives, certain performance requirements cannot be met for technical feasibility reasons. On this occasion, they must be altered to make the alternatives at issue feasible. In the second instance, cycling the alternatives through the optimization process in searching for the optimum mission systems may reveal that changes in some performance requirements will issue in a better solution to the design problem from the cost-effectiveness view. In other cases, these changes may also require changing mission requirements to meet these requirements through a changed set of performance requirements. The other existing line from the optimization process leads to the optimum mission systems identified by this process in a manner suggested by the cost-effectiveness equation. By now, the concept design can be accomplished by developing the primary characteristics of the systems not considered in the feasibility studies. The identification of more than one optimum concept design means that the “optimization curve” is reasonably flat over a limited range of alternatives – that there is little to choose among them.

Approaches and Techniques

There are two approaches of concept design: one is the empirical approach which is modeled by the design spiral and another is the systematic parametric analysis approach. Figure 2 shows a typical design spiral.

As is shown in Fig. 2, the design spiral consists of spokes and loops. The spokes stand for design considerations including performance requirements, arrangement, geometry displacement, hull structure, propulsion plant, electrical plant, command and surveillance, auxiliary systems, outfit and furnishings, energy summary, weight displacement, cost-estimate, and so on.

Concept Design, Fig. 1 Concept design of mission system (Allmendinger 1990)

The loops represent design iterations with the refinement of the design increasing as the loops spiral inward. The points identified alpha-numerically stand for certain stages. For example, 2B means the arrangement in the second loop.

Concept design feasibility studies are somewhat confined to the A and B loops of design spiral in the Fig. 2. The A loop is mainly considered with the approximate sizing of the submersible and utilize empirical formulations and similar design data extensively. Three major steps are

involved in the sizing process. Firstly, select the geometry and the major elements of the SWBS (Ship Work Breakdown Structure) systems. Secondly, obtain first estimate of sizing data for these systems. Thirdly, summarize these data to estimate the size parameters of total weight and displacement in the neutral buoyancy condition and the total cubic.

Concept design procedure from 1A to 12B based on Fig. 2 will be discussed in the following part.

Concept Design, Fig. 2 Design spiral (Allmendinger 1990)

A loop Step 1 – Performance Requirements

The basic inputs to the design process are those over-all mission requirements that are relevant to the design of the submersible. It includes task site and task work, the details of which are as following (Allmendinger 1990):

1. Task site

a. Location

1. Area of the world
2. Seafloor or water column site
3. Maximum operating depth

b. Type

1. Point or separated points – site at one point or more than one point separated by certain distances
 2. Line – site along lines of specified distances, as would be the case in a pipeline inspection mission
 3. Area – site over an area of specified dimensions, as would be the case in a seafloor area mapping mission
- ##### 2. Task work
- ###### a. Category

1. Inspection
2. Maintenance
3. Other
- b. Work objects
 1. General – a general description of the work object such as a buried pipe, an open-frame fixed platform, or a wet-well head
 2. Specified – as extensive information as possible needed to formulate adequate maneuvering and mission subsystems performance requirements facilitating proper vehicle positioning, vehicle orientation, and mating of tools and other equipment – a critical mission requirement in affecting the productive time of a submersible
- c. Task description
 1. Work to be performed – data to be acquired, nondestructive inspection to be performed, values to be replaced, and so forth
 2. Loads to be transported – from water surface to site or site to water surface or both. These loads are part of the overall payload which also includes weights of all items used exclusively in performing mission task work
- d. On-board personnel – required to accomplish certain work
 1. Number
 2. Type – one atmosphere or ambient pressure types
- e. Response time – time allotted for the submersible to reach to the work site, if critical in performing mission tasks

A loop Step 2 – Arrangement

Firstly, the submersible may be considered as consisting of the pressure hull, envelope, and all other forms of structures comprising it. In this stage, the designer should determine the type and number of the pressure hull which includes one-atmosphere type and ambient pressure type, the type of envelope which includes enclosed one and non-enclosed one. And the location of other items should also be considered at this stage. Inside the pressure hull, there are personnel

(in HOV) and all items of equipment to which they must have ready access. The items outside pressure hull include propulsion unit, high-pressure air bottles, main ballast tank, and so forth.

A loop Step 3 – Geometry

Geometries including shape and dimensions should be determined.

1. Pressure hull
 - a. Shape
 1. If the designed submersible works in shallow depths, then its shape is governed by hydrodynamic and arrangement considerations.
 2. If the designed submersible works in deep depths, then its shape is governed by structural considerations.
 - b. Dimensions

Dimensions are estimated from volume which pressure hull must enclose.
2. Envelope
 - a. Shape
 1. Enclosed envelope – envelope streamlined in direction of motion for relatively high forward or vertical speeds or both. If not streamlined, it should be a fair form to reduce the potential for entanglement and fouling
 2. Open-frame envelope – shape usually approximates a rectangular prism
 - b. Dimensions – the dimensions of length L, breadth B, and depth D, which can initially be estimated from the similar designs
 - c. Envelope volumes
 - d. Displacement of submersible

Steps 4–9 in A loop are categorized as SWBS (ship work breakdown structure) groups. Two of the sizing procedures should be followed in this portion of the A loop: (1) select major components of systems to be used with the particular design alternative under study and (2) obtain first estimates of sizing data for the systems selected.

A loop Step 4 – Hull structure

Fixed ballast and buoyancy are included. These systems can provide for neutral buoyancy,

zero trim, adequate stability, and a weight margin in design. The pressure hull is the main, pressure-resisting shell structure of the submersible. This hull is usually a ring-stiffened cylinder, closed with hemispherical heads, for shallow-depth submersible although other geometries may be used. An unstiffened sphere, or combination of spheres, is used for deep-depth submersibles.

A loop Step 5 – Propulsion plant

The propulsion plant is composed of all systems required to move the submersible in the ahead and astern directions under normal or emergency conditions. The propulsion power source which consists almost all of the batteries for untethered submersibles is included in this group.

A loop Step 6 – Electrical plant

The propulsion plant is composed of systems necessary to provide and distribute electric power to meet all of the submersible's needs, excluding propulsion. It is the nonpropulsion power sources for auxiliary, including electrical power generation system, power distribution system, lighting systems, and some special purpose systems.

A loop Step 7 – Command and Surveillance

The nature and the extent of systems composing command and surveillance system vary greatly depending on demands placed on them by mission performance requirements. It includes command and control system, navigation system, communication system, surveillance system, and special purpose system.

A loop Step 8 – Auxiliary Systems

- (a) Human systems (especially in HOV) – It is composed of crew and noncrew and personal effects brought on board.
- (b) Air, gas, and miscellaneous fluid systems, which are required to expel seawater from ballast tank and to provide hydraulic power.
- (c) Static control systems – Care must be taken that items associated with these systems which vary during the dive, such as seawater in the main ballast tank, are accounted for as loads under load to submerge.

- (d) Dynamic control systems – Only thrust-producing systems used exclusively for maneuvering are included in this subgroup.

A loop Step 9 – Outfit and furnishings

The weight and displacement are minute in these systems compared with others. And the space requirements of them should also be carefully considered. The size of ladders, lockers, seats, and hull insulation has great influence on the pressure hull volume and, hence, has a cascading effects on other design considerations.

A loop Step 10 – Energy Summary

The power-energy requirements for the SWBS systems should be summarized and the sizing data for the electrical and pneumatic energy storage systems should be estimated. At this point, the following should be considered: dive profile, bottom-work time, endurance, power users, power requirements, power totals and time, reserve energy, emergency energy storage, and energy storage capacity.

A loop Step 11 – Weight-Displacement-Center Summary

At this point, summarize weights and displacements of SWBS systems and their loads and achieve the submerged design condition criterion of neutral buoyancy, in which total weight is equal to the displacement.

A loop Step 12 – Cost Estimate Summary

Summary of cost estimates is deferred until Point 12B.

Above is the complete procedure of the A loop. The B loop procedures begin to develop the submersible and its SWBS systems in detail in order to refine sizing data, obtain cost estimates, and obtain assurance that design condition criteria of neutral buoyancy, zero time, and adequate stability can be acquired.

B loop Step 1 – Performance Requirements

Examine performance requirements according to sizing data created in the A loop. The requirements should remain the same unless these data indicate that certain requirements are excessive and may lead to unfeasible design. In this case,

the designer should consult with the owner to make some changes to the requirements.

B loop Step 2–3 – Arrangement and Geometry

At this stage, the first definitive view of the submersible is obtained, and the major components of the SWBS systems are located for the first time. These procedures are promoted by considering the two points together.

B loop Step 4–9 – The SWBS System Groups

These steps develop systems in sufficient detail to permit refinement of sizing data and close estimates of cost data to be made. More precise formulations and direct calculations are used in this portion of the B loop, which begin to analyze each system, breaking it down into its parts for study, increasing in detail as the design progress through the inner loops of the spiral.

B loop Step 10 – Energy Summary

It refines electrical power-energy profile and pneumatic storage system based on more precise B loop SWBS data.

B loop Step 11 – Weight-Displacement-Center Summary

Using the more refined sizing data, it obtain a more accurate estimate of fixed ballast or buoyancy, a check on the vertical distribution of weights and displacement necessary for adequate stability, and a check on the longitudinal distribution of weights and displacements required for zero trim.

B loop Step 12 – Cost Estimate Summary

It summarizes estimates of first and annual operating costs associated with the SWBS systems selected for a particular design alternative (Allmendinger 1990).

Systematic Parametric Analysis

Approach – Optimization Programs

These programs permit a very large number of concept design alternatives to be investigated, which increases the probability that the optimum concept design will be identified. Design procedures are formalized by establishing mathematical relationships between dependent design variables and independent design variables

or parameters. These relationships or parameter equations in the program permit rapid evaluation of design parameter changes on the dependent variables. And the explicitness of optimization program is useful in facilitating discussion between owners and designers regarding any aspect of the mission requirements or the design in question.

The above introduction mostly came from Allmendinger (1990). More detailed introduction can be found from Busby (1990) and Funnel (1999).

Key Applications

Concept design is an irreplaceable step of the design of submersible. Christ and Wernli (2014) dis reviewed the technology of ROV and then delve into the theoretical basis for ROV operations (including stability and drag computations) and also reviewed the standards surrounding the industry in general. Correa et al. (2015) introduced architecture for the conceptual design of remotely operated vehicles (ROV). Guo and Lin (2011) developed an underwater vehicle which can adjust its attitude freely by changing the direction of propulsive forces. Li et al. (2011) introduced the design of P-SURO AUV which is a test-bed for developing underwater technologies. The team of biologists and engineers considered the concept design of a bionic autonomous underwater vehicle (AUV) that uses the pectoral fins to achieve high maneuverability (Fish et al. 2003). ARV, a hybrid kind of submersible, can be considered as the combination of ROV and AUV. The design of *Nereus* (Bowen et al. 2008) is an important attempt of the design of ARV.

[\(Concrete Gravity-Based Structures\) CGBS](#)

Definition

A *CGBS* is generally a very large and extremely heavy reinforced concrete structure which is placed on the seabed. It withstands the extreme environmental forces by virtue of its own weight and inherent strength.

CGBS platforms are among the largest and most impressive structures ever built and moved by man. To date the *Troll platform* is installed in the deepest water (303 m), and the *Hibernia platform* is the heaviest weighing 1.2 million tons on land. The designs of *CGBSs* vary considerably, and their weights range from 3000 to 1.2 million tons with corresponding topsides weighing between 650 and 52,000 tons.

A typical *CGBS* has a concrete base (often called a caisson) with one or more shafts to support the topside platform. When empty, voids within the base known as cells (along with the hollow shafts) provide buoyancy during the latter stages of construction, tow-out, and installation. When a *CGBS* is in operation, the cells are flooded with seawater or act as storage and in some cases separation facilities for crude oil (<https://www.iogp.org/bookstore/product/decommissioning-of-offshore-concrete-gravity-based-structures-cgbs-in-the-ospar-maritime-area/>).

Basic Characteristics of Concrete Platform

The concrete platform is a type of fixed platform which stands on the seabed by means of its huge weight. The bottom of a concrete gravity platform usually consists of many huge concrete caissons that support the deck structure with three or four hollow concrete legs. Caissons in the bottom are usually cylindrical and can be used as oil tanks or ballast tanks, as shown in Fig. 1. The weight of this type of platform is up to hundreds of thousands of tons. Table 1 shows the dimensions and weights of typical concrete gravity platforms. Thanks to its huge weight, the platform can directly sit on the seabed. However, due to the heavy weight of concrete platform, the condition of the seabed must be strong enough to bear the huge weight. So the concrete gravity platform is generally located on the seabed with dense sand.

Concrete platforms can be used for drilling, oil extraction, oil storage, and so on. The water depth that concrete platforms can work well is within 200 m and the best from 100 to 150 m.

Concrete platform has its own advantages and disadvantages.

The advantages of concrete platforms are:

- (a) Save steel and economical. The total cost of constructing a concrete gravity platform is lower than that of the steel jacket platform.
- (b) The installation workload at the sea site is small.

- (c) Anti-seawater corrosion, low maintenance costs, and long service life.

The disadvantages of concrete platforms are:

- 1. Require good seabed conditions.
- 2. The structural analysis and manufacturing process are complicated.
- 3. Reuse is difficult.

History of Concrete Platform

At the end of 1969, industrial oil was discovered in the Ekofisk field of the North Sea. However, due to the harsh sea conditions in the North Sea and the surging price of steel at that time, it is difficult to adopt the traditional steel jacket platform. Then, the Norwegians built the first concrete gravity platform. In the design, the Norwegians used their experience of building concrete breakwaters and offshore gravity light-houses, as well as the abundance of concrete in

Concrete Platform, Table 1 The dimension and weight of typical concrete gravity platforms (Sharp 1979)

Water depth	141 m
Production capacity	150,000 barrels/day oil
Storage capacity	550,000 barrels
Caisson base area	10,340 m ²
Caisson height	57 m
Weight of substructure in air	283,000 tons
Total height of platform	168 m

Concrete Platform, Fig. 1 A concrete gravity platform

Norway. This concrete gravity platform was designed in 1970 and started to be built in 1971 and was finished in June 1973. This concrete platform with 92 m diameter, about 100 m high, has an oil storage capacity of 158,900 m³. The successful construction of this platform provided valuable experience for the future use of concrete gravity platforms in the North Sea and other parts of the world.

Concrete platforms can be used for drilling, oil extraction, and oil storage and transportation. It has the advantages of saving steel, anti-seawater corrosion, low maintenance costs, and long service life. So 17 concrete platforms were built in the North Sea and off the coast of Brazil in just 5 years from 1973 to 1978. The maximum depth of these platforms' operating depths is 150 m and the minimum depth 15 m.

However, some shortcomings of the concrete platform appeared gradually, and in the early stages of development, some problems emerged. For example, the concrete gravity platform requires good seabed condition during working and deepwater depth during construction. These problems made it difficult to promote the concrete gravity platform to other waters in the world. At the same time, due to the improved techniques of steel jacket platforms, steel jacket platforms became popular again. This reduced the demand for concrete platforms.

After 1984, the advantages of concrete platforms were recognized by some oil companies, and orders started to increase gradually. The concrete platform at this time has the following characteristics:

- (a) From medium water depth to shallow and deepwater depth.
- (b) Safer and more reliable concrete gravity platform appeared.

Structural Components of Concrete Platform

Concrete platform contains a cellular base, columns, and deck structure. Figure 1 also shows the

structures of a concrete platform. The cellular base is the foundation of the entire building. In order to resist the huge storm force, the platform requires a large base structure. To prevent the base from sliding on the surface of the sea floor, skirt plates could be inserted into the seabed around the base. Large base structure can be used to store crude oil, which provides the concrete platform the advantages of oil storage.

The deck provides a workplace for production. The deck is fitted with various production and living facilities.

The column is connected between the base and the deck, to support the deck.

Construction and Installation Process of Concrete Platform

Gravity platform construction process is complicated, compared to those of other types of offshore platforms. Basically, there are two construction methods for concrete platform. One is that the building site can be located at the low-lying water area that is drained. The other is that construct the base on the land to a certain extent and then launched into the water.

The construction of concrete platform normally consists of the following steps:

- (a) In the dry dock, construct the base to a predetermined height and pour water into the dry dock.
- (b) Tug the base together with lifting equipment to the deepwater storm-sheltered area, and moor it firmly.
- (c) Continue building the upper part of the base and the legs until the concrete base and concrete legs are constructed completely.
- (d) Ballast the base, and the platform goes down. Then the prefabricated platform deck is transported by barges right up to the legs. Drain the base, and the legs float up a little until the legs support the deck at the right positions.
- (e) Connect the legs and the deck firmly together, forming a concrete gravity platform.

The Strength of Concrete Platform Main Structures

The strength of a concrete platform is highly important, and it is a basic problem needed to be considered when engineers design a concrete platform. However, sometimes it was still neglected and an accidental example is provided here.

On August 23, 1991, the loss of the Sleipner A concrete gravity platform caused huge economic losses (Collins et al. 1997). The concrete base structure of the Sleipner A platform was lowered into the Gandsfjord for deck-mating. When deck-mating, a Condeep structure was about 20 m deeper than it is during operation. The Condeep structure experienced the critical hydrostatic pressure. This high pressure caused the cell wall to break, allowing water to rush into the drill shaft. Later, the structure sank. As the structure went deeper into the fjord, the buoyancy cells imploded. Finally, this structure of \$180 million dollars was totally lost. Only the pile of rubble at the bottom of the fjord remained.

This accident gave a big lesson on the structural design for concrete platform. The design of concrete gravity platforms should consider the buckling or crushing of the cellular base bulkhead. When the base is also used as a storage tank, temperature stress due to internal and external temperature differences should be considered. In addition, when the concrete gravity platform works in the area with high seismicity, the seismic performance of the platform has to be considered. The water-structure interaction and soil-structure interaction have much importance in the analysis of offshore concrete gravity platform. Besides, the inelastic behavior of the hollow concrete members deserves attention (Whittaker 1987).

Furthermore, because concrete platforms mostly work in the North Sea, where ice may be expected in the winter, the ice-concrete interactive effect has also to be taken into account if the concrete gravity platform works in the ice zone. Level ice on offshore concrete platform is the main concern for general concrete abrasion, and

the other type of ice, for example, iceberg and freshwater ice, should not be forgotten (Tijssen 2015). Concrete abrasion mainly occurs below water level, because level ice adheres to the concrete above water level.

Connectors of mobile offshore base (MOB); Elastic connectors; Flexible connectors; Hinge connectors; Rigid connectors; Rigid Module and Flexible Connector (RMFC); Semirigid connectors

Definition

A very large floating structure (VLFS) system is usually composed of a number of modules.

Connectors of VLFS are used to connect different modules of a VLFS system (see Fig. 1). For multimodular floating systems, the connector between modules becomes the weakest component in the whole system, which is subjected to large loads and is easily damaged.

Scientific Fundamentals

Connector Types

The connectors could be designed as different types for different purposes and ocean conditions, as well as beneficial for the fabrication, transportation, installation, and even potential expansion of the practical VLFS system. In general, there are the following types of connectors:

1. The rigid connectors (the fixed connectors): Adjacent modules are fixed together with no relative motion in all degrees of freedom.
2. The hinge connectors (the pin joints); see Fig. 2: Adjacent modules can move **freely in pitch mode** and move together (with no relative motion) in the other five degrees of freedom.

Connectors of VLFS, Fig. 1 Sketch of multimodular floating systems (Shi et al. 2018)

Connectors of VLFS,**Fig. 2** The hinge connector (Yu et al. 2003)**Connectors of VLFS,****Fig. 3** The semirigid connector (Yu et al. 2003)

3. The semirigid connectors (the hinge connectors with an additional linear rotational spring), see Fig. 3: Compared with the hinge connectors, as for the semirigid connector, the relative pitch motion of adjacent modules will be **affected by the additional rotational spring**.
4. The hinge connectors with an additional rotational damper: Adjacent modules can move in **pitch mode affected by the damper** and move together (with no relative motion) in the other five degrees of freedom.
5. The flexible connectors (the chain-type connectors and the compliant connectors) shown in Fig. 4: The connectors could be elastic cables, which can only provide a relative constraint between the connection points of the adjacent modules. The adjacent modules have considerable relative linear displacement (surge, sway, heave) that is affected by the elastic properties of the connectors and can move **freely in three angular** displacement degrees (roll, pitch, yaw).
6. The elastic connectors (see Fig. 5): The connectors could have **one or several degrees of elastic deformation** under outside loads. The adjacent modules have relative smaller motions that are affected by the elastic properties of the connectors.
7. The fixed connectors **with connection gaps** (see Fig. 6): Adjacent modules can freely have smaller amounts of movement in several degrees because of the gaps. However, after a small amount of movement, the connectors work as rigid connectors, hinge connectors, elastic connectors, etc.

Simplification of Connectors in the Hydroelasticity Analysis of VLFS

The Very Large Floating Structure (VLFS) is a unique concept of oceanic structures proposed for potential applications, such as floating airports, storage facilities for oil and natural gas, military and emergency bases, floating farms, and so on (Wang and Tay 2011). Because of the large scale

Connectors of VLFS, Fig. 4 The flexible connector (Shi et al. 2018)

Connectors of VLFS, Fig. 5 The elastic connector (Xia 2018)

Connectors of VLFS, Fig. 6 The fixed connectors with connect gaps (Fu et al. 2005)

of the horizontal directions of a VLFS, they are usually composed of a number of standardized or different types of modules with different types of connectors.

For the flexible/elastic connectors, if we simplify each module as a rigid body, the flexibility of the whole modular VLFS system will mainly occur in the connectors (Riggs et al. 2000). However, for the rigid or the fixed connectors, we could not simplify each module as a rigid body because the elastic deformations of the whole structure will be significant, occurring not only in the connectors but also in all the modules. Many research results show that the stiffness of the connectors strongly influences the hydroelastic responses of the VLFS and the loads on the connectors (Khabakhpasheva and Korobkin 2002; Fu et al. 2007; Wang et al. 2009; Gao et al. 2011; Michailides et al. 2013; Ren et al. 2019).

A comparative study of rigid-module-flexible-connector (RMFC) and finite-element-analysis (FEA) models for the hydroelastic analysis of a mobile offshore base (MOB) VLFS has been performed by Riggs et al. (2000). The results indicate that the simplified RMFC model with proper corresponding parameters can predict as well as the refined FEA model. Therefore, the RMFC model may be a suitable selection for hydroelastic analysis of the modular VLFS system for its short time-consuming. A generalized network model based on the RMFC model has been proposed and developed for modeling the modular VLFS system with arbitrary structure topology (Xu et al. 2014; Zhang et al. 2015b, 2017b; Xia et al. 2016).

Effects of Different Types of Connectors

The types of VLFS are usually the pontoon-type and semisubmersible type. From a dynamic point of view, the VLFS is different from the conventional floating structures. For the large scale of the horizontal directions, as well as the existing of elastic or flexible connectors, the stiffness is relatively small and its behavior on the water surface is similar to that of an elastic thin plate. Hydroelasticity theories (Betts et al. 1977; Bishop and Price 1977; Jensen and Pedersen 1981; Wu

1984; Price and Wu 1985; Bishop et al. 1986; Wu et al. 1991a, b, 1997; Jensen and Dogliani 1996; Xia and Wang 1997; Chen et al. 2003a, b, 2004, 2006a, b, 2010, etc.) were employed to check the conceptual design of a kind of very large floating airport of a length from hundreds to thousands meters or larger (Wang et al. 1991; Du and Ertekin 1991; Ertekin et al. 1993) during the last century and in the early part of this century.

A research project of Mobile Offshore Bases (MOB) executed by the Office of Naval Research (ONR) of the USA and a Japanese national project by the Technological Research Association of Mega-Float (TRAM) are two landmark projects with great influence on the development of VLFS technology. For the purpose of deducing the loads in the structure, as well as for convenience of construction and transportation, the types of multimodular floating structures with connectors are preferred. Thus, the connector becomes a key component for the multimodular floating structures, and the connection load becomes a critical issue for the design of modular connection.

Different kinds of connectors have been proposed for modular connections. The simple hinge connector is the most common one first proposed for VLFS. This type of the connector completely releases the pitch motion among modules so that the bending stress in the structure is greatly reduced but translational loads of the hinge connector are still large.

Compared with hinge connector, the compliant connector or the so-called flexible connector can significantly reduce the connector loads with some tolerances on structural flexibility. In this regard, the compliant connector, enhanced compliant connector, and modified compliant connector were sequentially proposed (Haney 1999). Riggs et al. (1999) studied 13 different connector stiffness cases, in which the longitudinal and vertical stiffness varied and the transversal stiffness was fixed at a large value. The results indicated that different stiffness cases might have different impacts on the system dynamic responses and connector loads. Xia et al. (2000) investigated the hydroelastic behavior of two-dimensional articulated plates connected by idealized connectors that were treated as a series of flexural

rotational springs and vertical linear springs. It indicates that the hydroelastic response strongly depended on the stiffness of the springs and the incoming wave frequency.

A prototype design of a flexible connector is associated with the stiffness configuration and the strength analysis. Since the stiffness of flexible connectors has a great impact on the connector loads and the responses of multimodular floating systems, the stiffness configuration is therefore a precondition of strength analysis. Some efforts have been made to understand the effect of the stiffness on the responses of multimodular floating systems. A multiplate floating system connected with torsion springs was studied, indicating that the torsion spring stiffness greatly influences the vibration amplitude of the main structures (Khabakhpasheva and Korobkin 2002). The effect of the stiffness of semirigid connectors on the hydroelastic response of VLFS was studied by Fu et al. (2007). Their results show that the stiffness of the connectors and the modules is very important in determining the hydroelastic response of the structure as well as the characteristics of the bending moment distribution.

Riyansyah et al. (2010) and Gao et al. (2011) investigated the effect of the location and rotational stiffness of the connector for reducing the hydroelastic response and stress resultants of the VLFS. They found that appropriate position and stiffness of connectors could improve the response of the floating system.

A modular multipurpose floating structure (MMFS) conceptual system utilizing a number of standardized modules is proposed by Ren et al. (2019). Different typical outermost connector designs have been proposed and investigated for the MMFS system. Different connector types of the outermost module can strongly influence the hydrodynamic responses of the MMFS system. The more rigid outermost connector tends to induce much larger responses of the shear force and the bending moment of the inner connectors. Hinge type outermost connectors can significantly reduce the responses of both the shear force and the bending moment of the most loaded connectors. By adding a proper linear pitch damper to the

outermost hinge connector, it can effectively reduce the motion of the outermost module, and produce considerable wave energy. The results indicate that the longer outermost module with the hinge connection may be an effective way to reduce both the loads on connectors and the motion of the outermost module.

Designation of Different Types of Connectors

Rognaas et al. (2001) put forward a flexible connector design with tolerance in the pitch and yaw motions, where elastomeric bearings, hydraulic jacks, and fenders were utilized to provide elastic supports, and steel cables undertook axial tensile forces. Except for utilizing rubber cushions or cables as compliant components, springs are generally applied to provide elastic connection. Xu et al. (2014) proposed a kind of flexible connector with trapezoidal rubber cushions and cables, where the rubber cushion is mainly used to constrain the longitudinal and transversal motions between adjacent modules when the compression occurs, and the cable is used to constrain the longitudinal motion between adjacent modules when the tension occurs. Four orthogonal linkages equipped with springs were used to restrain the linear displacements where angular rotations were allowed (Wu et al. 2016).

Xia et al. (2016) designed a special elastic connector with air-springs, which could alter the stiffness of connector to reduce the oscillation of floating structures by changing the air pressure of the air-springs. Although different designs exhibit their own distinguishing features, what is common is that these flexible connectors provide elastic constraints so that the load level in structure can be ameliorated. Zhang et al. (2017b) proposed three types of flexible connector configurations to represent anisotropic stiffness models and investigated the effect of the different stiffness on the global stability of the multimodular floating system with amplitude death mechanism (Zhang et al. 2015a) where a preferred parameter domain for the stiffness and wave period was suggested.

A variety of connections (Tan et al. 2018; Zhang et al. 2017a) utilized in ocean production systems have been widely investigated to provide guidance for structural optimization. Zhao et al. (2019) studied a general strategy for resolving the stiffness configuration for flexible connectors in various wave conditions. In numerical studies of an eight-module floating system, the optimal stiffness configuration is found in a full scenario of weight combinations. It indicates that the combination of small longitudinal stiffness, large transverse and large vertical stiffness is favorable for most wave conditions.

Cutting Technology of Steel

Kim Hyunwook

School of Naval Architecture and Ocean Engineering, Dalian University of Technology, Dalian, Liaoning, China

Definition

Ships and marine structures are made of thousands of welded and assembled members, which are made of ship steel. The technological process of making steel plates and profiles into hull members is called hull steel processing, and cutting technology of steel is also a part of hull steel processing, including mechanical cutting, flame cutting (gas cutting), plasma cutting, and laser cutting. With the development of hull construction technology, the processing technology of hull members tends to the direction of highly efficient processing equipment, numerical control, and operation assembly-line (Liu and Wang 2011).

Mechanical Cutting

Mechanical cutting refers to the process of applying to the material a mechanical cutting force exceeding the ultimate strength of the material, which causes the extrusion and the fracture separation of the material. Helical sword square shears and pressure shearing machines are the two main kinds of machines for cutting straight edge components in hull processing workshops, while the disc shearing machine is mainly used for mechanical cutting of curve edge components (Enomoto et al. 2012).

Flame Cutting (Gas Cutting)

Flame cutting usually refers to the oxy-acetylene cutting or oxy-propane cutting, the essence of which is the chemical process of metal burning in oxygen (Huang 2013). Generally, it can be divided into three stages: preheating, combustion, and slag removal. In gas cutting, first of all, the metal is heated by the adjusted preheating flame, so that the temperature of the starting point of the cutting seam gradually rises until it reaches the burning point of the metal. Next, a high-pressure flow of pure oxygen is released, causing the metal to burn (vigorous oxidation) and rapidly blowing off the slag (metal oxide) generated by the combustion. By continuing the above process, a smooth slit could be formed in the cut metal to separate the metal, as shown in the Fig. 1. In the hull processing workshop, manual gas cutting torch, semi-automatic gas cutting machine, portal automatic cutting machine (Fig. 2), and other equipment are often used for cutting the edge of components. The portal automatic cutting machine is equipped with many cutting torches, which are mainly used for the straight-line cutting of steel plates, and those cutting torches can be operated simultaneously with high cutting efficiency.

Cutting Technology of Steel, Fig. 1 Gas cutting

Cutting Technology of Steel, Fig. 2 Portal automatic cutting machine

Plasma Cutting

Plasma cutting is a processing method using high temperature plasma arc heat to partly melt (and evaporate) the metal at the incision of the work-piece, and forming the incision through the use of the momentum of high-speed plasma to exclude molten metal. It produces a temperature five to six times that of the average arc, and a flow rate of up to above 1500 m/s. Therefore, this method can be applied to cutting copper, aluminum, stainless steel, and other high temperature refractory metals which cannot be cut by gas flame. It should be noted that the method is especially suitable for cutting sheet, with a cutting speed three to six times that of flame cutting. Because of its high cutting speed and excellent cutting quality, plasma cutting has a great potential to replace gas flame cutting for cutting steel plate in shipbuilding (Xu 2005).

Semi-dry plasma cutting, dry plasma cutting, and underwater plasma cutting are three main ways of plasma cutting. Semi-dry plasma cutting (also known as water-cooled cutting) uses the force of the high-speed ionized airflow ejected from the torches to separate the molten metal to form a cut. Dry plasma cutting (also known as air-cooled cutting) uses the air compressor to inject air to the seam of the plate to achieve the cooling

effect, which has a lower cost, but a greater pollution. Underwater plasma cutting uses the plasma arc to perform cutting in the water curtain or water, and uses the water to separate the plasma arc column from the air. Most of the metal dust generated by underwater plasma cutting is deposited in the water, and the frequency and intensity of noise are also greatly reduced, so the pollution of such cutting to the environment is limited (Li and Wei 2006).

Plasma cutting is not only faster, but has higher production efficiency and better incision quality. To be specific, the plasma arc incision is narrow and flat, with relatively small heat-affected area and deformation. Thus, numerical control plasma cutting machine is increasingly used in shipbuilding (Fig. 3) (An et al. 2020).

Laser Cutting

The application of laser cutting technology originated from the late 1970s. There are two forms of industrial laser machines, namely gas (such as CO₂) laser machines and solid (such as neodymium and yttrium aluminum garnet) laser machines, with different design and structure. The energy generated by laser can reach up to between 1×10^5 and 1×10^6 W/cm², which is fully adequate to melt metal. Therefore, laser can be

Cutting Technology of Steel, Fig. 3 Plasma cutting

used for metal cutting, and has many advantages – high cutting precision, good surface quality, high cutting speed, small thermal deformation, narrow notch width – compared with flame, plasma, and other cutting technology (Yilbas 2004).

Laser cutting can be generally divided into oxide assistant cutting and fusion cutting, of which the former is the most widely used. Oxide assistant cutting uses laser as the heat source for preheating, and oxygen and other active gases as the cutting gas. The gas ejected, on one hand, reacts with the metal being cut, oxidizes it and releases a large amount of oxidation heat; on the other hand, blows the molten oxides and fusion products out of the reaction zone to form a cut in the metal. The faster oxide assistant cutting speed is associated with a smaller thermal penetration and a better cutting quality. During laser fusion cutting, the metal is melted by laser heating; non-oxidizing gases (argon, helium, nitrogen, etc.) are ejected through the torch coaxial with the beam; the liquid metal is discharged by high pressure of the gas; thus an incision is formed.

Laser fusion cutting is mainly used for cutting some nonoxidizing materials or active metals. In its applications, oxygen is used as cutting gas for cutting non-alloy steel, while nitrogen is used for

cutting stainless steel, aluminum, and aluminum alloys (Shemshadian et al. 2020).

[Damaged ship stability](#); [Stability of damaged ship](#)

Definition

Damage stability of a ship mainly refers to the ability of the ship to resist capsizing and restore the equilibrium position in calm water and waves, and it requires that the ship can still have sufficient buoyancy and stability after one or several damaged compartments. The water flow into the ship through the damaged compartment will change the ship's buoyancy, the ship's motion response, and dynamic stability in waves, and even cause the ship to capsize or sink. Damage stability is one of the most basic and important ship performances which is related to the safety of ship navigation at sea. Due to the complexity of the marine environment, the catastrophic events caused by the damaged instability often occur, which cause huge property losses in the light, a large number of casualties, and serious environmental pollution. Therefore, improving the ship stability under

damage conditions, especially the environmental adaptability and survivability of ships under severe sea conditions, has always been the main goal of the ship overall performance research.

Introduction

In the past, the ship damage stability problem had received little research attention, mainly because the numerical as well as experimental treatment of progressive flooding and capsize in a random seaway represents a very difficult undertaking. As a result, quantitatively specific standards of residual stability have been introduced for the first time in the 1960 SOLAS Convention which only address the metacentric height (0.05 m) (22nd ITTC).

However, a number of major disasters involving a large loss of life have forced development in international regulations based either on deterministic or probabilistic approaches to assessing damage stability but ignoring in the main the physics of the problem at hand (22nd ITTC).

Subdivision and Stability

Ship subdivision and layout are two of the most important issues affecting ship performance, functionality, and safety. The subdivision of a ship is considered sufficient if the attained subdivision index A is not less than the required subdivision index R according to the subdivision and

damaged stability provisions of SOLAS'90. For the calculation of required subdivision index R and attained subdivision index A, there are several key factors as follows:

Subdivision length (L_s) of the ship is the greatest projected molded length of that part of the ship at or below deck or decks limiting the vertical extent of flooding with the ship at the deepest subdivision draught.

Mid-length is the midpoint of the subdivision length of the ship.

Aft terminal is the aft limit of the subdivision length.

Forward terminal is the forward limit of the subdivision length.

Length (L) is the length as defined in the International Convention on Load Lines in force.

Freeboard deck is the deck as defined in the International Convention on Load Lines in force.

Forward perpendicular is the forward perpendicular as defined in the International Convention on Load Lines in force.

Deepest subdivision draught (ds) is the waterline which corresponds to the summer load line draught of the ship.

Light service draught (dl) is the service draught corresponding to the lightest anticipated loading and associated tankage, including, however, such ballast as may be necessary for stability and/or immersion.

Partial subdivision draught (dp) is the light service draught plus 60% of the difference between the light service draught and the deepest subdivision draught.

Permeability (m) of a space is the proportion of the immersed volume of that space which can be occupied by water.

Machinery spaces are spaces between the watertight boundaries of a space containing the main and auxiliary propulsion machinery, including boilers, generators, and electric motors primarily intended for propulsion. In the case of unusual arrangements, the administration may define the limits of the machinery spaces.

Watertight means that in any sea conditions water will not penetrate into the ship.

Watertight means having scantlings and arrangements capable of preventing the passage of water in any direction under the head of water likely to occur in intact and damaged conditions. In the damaged condition, the head of water is to be considered in the worst situation at equilibrium, including intermediate stages of flooding.

Deadweight is the difference in tonnes between the displacement of a ship in water of specific gravity of 1.025 at the draught corresponding to the assigned summer freeboard and the lightweight of the ship.

Lightweight is the displacement of a ship in tonnes without cargo, fuel, lubricating oil, ballast water, fresh water and feedwater in tanks, consumable stores, and passengers and crew and their effects.

Stability and Motion

When the side or bottom of one or more cabins are damaged due to collision, grounding, and other accidents, the external fluid will flow into the cabins through the breach holes, and then the fluid inside the breached cabins will flow into other adjacent cabins through the connection openings.

The performance of a damaged ship in waves is affected by both the external wave excitation and the hydrodynamics load generated by the liquid sloshing in the cabin, and the time domain motion of the damaged ship also affects the dynamic characteristics of the flooding. When the external waves enter the damaged cabin, the parameters of the ship (mass, buoyance, etc.) will change, causing the problem of liquid sloshing inside the damaged ruined cabin. The load generated by liquid sloshing will further affect the motion characteristics of the ship in turn. In this process, the motion of the damaged ship and the flooding water is coupled with each other. The research on the floodwater and the motion of the damaged ship in waves is extremely complex, involving many influencing factors.

In general, the flooding process that follows the creation of the damage opening can be divided into three main phases (IMO SLF46/INF.3 2003).

Damage Stability, Fig. 1 Main phases of the flooding process

Due to the large pressure difference, water will rush into the damaged compartment, and this phase can be called as transient flooding phase. After that, the water will flood to undamaged internal cabins through internal connection openings, and this phase can be called as progressive flooding phase. At the end of flooding, the ship will capsize/sink or reaches a final steady state. A schematic representation of these phases is given in Fig. 1.

The establishment of the prediction method has consistently been the focus of ITTC wave stability research. According to the physical phenomena involved in the damaged flow, ITTC divides it into three problems (ITTC 2005):

Damaged vessel dynamics: It generally refers to the ship with zero forward speed drifting on the free surface under the excitation of waves. At present, the research on the motion of a damaged ship with forward speed is also a hot topic. Nonlinear 6DOF seakeeping model that allows the vessel to drift as well as allows for changes with time in its mass, the center of mass, mean attitude, environmental excitation, and hydrodynamic reaction forces can be used for these problems (25th ITTC).

Water ingress/egress: This refers to the flooding phenomenon itself, namely the process of water inflow and outflow through the damaged openings and the progressive flooding through internal space. An adequately accurate water ingress/egress model that allows for multiple-compartment flooding in the presence of oscillatory flows and at time of shear flows in

extreme wave conditions is a prerequisite to undertaking any investigations on damage survivability. CFD method is the main method to study these problems at present (25th ITTC).

Floodwater/Vessel interaction: It refers to the behavior of the accumulated floodwater inside the ship's compartments and its interaction with the ship. A study of damage survivability involves two distinct but intrinsically interrelated and highly interacting processes, namely ship motion and flooding. Vessel motion influences considerably and directly the flooding process and conversely, flooding affects both the vessel motion and her attitude. It is essential, therefore, to take both phenomena into consideration when studying the evolution of either. However, the nonstationarity in the vessel motion introduced by the water accumulation coupled with the intermittence of the flooding process itself and the severe nonlinearities in the ensuing dynamic system demand great care in dealing with the various issues of this complex problem (25th ITTC).

Typical Accident

Damage stability is usually caused by collision, grounding, and contact. According to EU statistics of ship accidents from 1958–2009, it is found that there are 1016 accidents caused by collision, accounting for 66.54%.

In September 1994, the Baltic ferry MS Estonia sank, due to rapid loss of stability after loss of her hull integrity and ingress of seawater on the car deck through the bow ramp. More than

900 people were killed in one of Europe's worst ferry tragedies. The ship sank in about 30 min, just after midnight when most of the passengers were asleep. This vessel complied with damage stability requirements of SOLAS'74 (launched in 1980), while compliance with the later SOLAS'90 is uncertain (the ship was at the time of operation treated as an *existing ship* in terms of compliance with latest regulations) (Christianson and Engelberg 1999).

Key Numerical Method for Damages Ship Stability in Waves

The dynamic performance of damaged ships in waves is constantly changing, which leads to high nonlinearity of the dynamic system. Therefore, an effective method to reproduce the extreme nonlinearity of the ship motion and the process of the damaged flow is to solve it in the time domain. Up to now, many works have been devoted to the study of the damaged ship motions in waves.

The assessment of damaged ship motion is normally based on potential theory. The wave forces and hydrodynamic forces are usually calculated by potential theory, the same way as the intact ship; the internal water surface is assumed to be horizontal or a free-moving plane, and the inflow and outflow of water through the damaged opening are calculated by the modified empirical formulas (Vassalos et al. 1997; Lorkowski et al. 2014; Qian et al. 2000; Manderbacka et al. 2015; Lee 2015; Acanfora et al. 2019). Furthermore, roll damping coefficients due to floodwater are usually calculated by the empirical method. One degree of freedom (roll motion) to six degrees of freedom can be utilized to the simulation of damaged ship motion in waves.

With the development of technology, a fully viscous method is used for the capture of the dynamic characteristics of the flooding process (Shen and Vassalos 2009; Strasser 2010; Touzé et al. 2014; Gao and Vassalos 2015). However, we should also be aware of the simulation of the damaged ship motion coupled with the damaged flow by a fully viscous method which is unrealistic for the engineering application due to the high computational costs at present.

The coupling between the damaged ship motion in waves and the damaged floodwater is a very complex problem. The in-waves calculations need to consider not only the motions of the damaged ship but also the strong nonlinear floodwater dynamics as well as progressive flooding. Particularly, despite several studies that focused on the relationship between flooding water and the motion response of a damaged ship, the effects of flooding dynamics on the motion of a damaged ship are not yet clearly understood.

Considering that CFD method can simulate most of the flow characteristics and parameters, and the potential flow method has a strong advantage in solving seakeeping problems. Therefore, the coupling method of CFD and potential theory can be utilized to reduce the computational cost on one hand, and to simulate the flow problem more efficiently on the other hand. Cho et al. (2006) developed a numerical method that combines the three-dimensional frequency domain panel method and modified VOF method, which can take the internal flow and sloshing into account. Gao et al. (2013) combines strip theory and RANS equation for the simulation of damaged ship motion. Hashimoto et al. (2015) simulated the transient behavior of ships by coupling the three-dimensional MPS method with the strip method. Bu and Gu (2020), Bu et al. (2020, 2021) proposed a unified viscous and potential prediction method (UVPP) that combines CFD and potential theory to investigate the hydrodynamics of floodwater and its effects on the damaged ship motions. In this method, the three-dimensional time domain hybrid source method is employed to the calculation of damaged ship motion in waves, and

Damage Stability, Table 1 Main ship particulars

	Full scale	Model scale
L_{OA}	179 m	4475 mm
L_{BP}	170 m	4250 mm
B	27.8 m	695 mm
T	6.25 m	156.3 mm
$D_{CARDECK}$	9 m	225 mm
$Disp.$	17300ton	270.3 kg
KG	12.89 m	322 mm
GM	2.63 m	65.8 mm

the fully viscous method is employed to the simulation of the flooding process. They have proved the accuracy and efficiency of this method both in calm water in waves.

Influencing Factors on Numerical Simulation Results

The damaged Ro-Ro passenger vessel is adopted for the investigation of influencing factors on numerical simulation results (ITTC 2002), which was once used for the benchmark study of

damaged ship stability. The model tests were conducted in the Denny tank according to the model test method of Imo SOLAS’ 95 Resolution 14 (ITTC 2002). The main ship particulars are listed in Table 1, and the body lines are shown in Fig. 2.

Effects of Calculating Method for Froude-Krylov and Hydrostatic Forces

Four degrees of freedom (sway-heave-roll-pitch) is adopted to calculate the motion response, and the wave height of 1.2 m is selected. Two methods were used for the calculation. In one method, FK

Damage Stability, Fig. 2 Ship body lines and midship damaged case (ITTC 1999)

and hydrostatic forces are integrated along the instantaneous wet surface of the hull, while FK and hydrostatic forces are integrated along the average wet surface of the hull in the second method. The comparison results are presented in

Damage Stability, Fig. 3 Effects of calculation method for FK and hydrostatic forces on roll motion

Damage Stability, Fig. 4 Effects of degree of freedom on roll motion

Fig. 3. It can be seen that the calculation results using the average wet surface integration are larger than the model test results, and the calculation results considering the instantaneous wet surface are in good agreement with the model test. Thus, it can be inferred that the instantaneous wet surface needs to be considered in the simulation of damaged ship motion.

Effects of the Degree of Freedom

Differences between the 1DOF roll motion mathematical model and the 4DOF mathematical model are compared, as shown in Fig. 4. The current calculation results show that there is little difference between the calculation results of the 1DOF mathematical model and the 4DOF mathematical model, which are in good agreement with the model test results.

The Effects of Wave Height

The 4DOF mathematical model and the method based on the instantaneous wet surface are used to calculate the roll motion at different frequencies and compared with the model test results. The comparison results are shown in Fig. 5. It can be seen that the calculation results are in good agreement with the model test. The difference of unit roll amplitude calculated by wave height 1.2 m and wave height 2.4 m explains the nonlinearity of the problem. Therefore, the linear method is no longer suitable for calculating roll motion. It can also be seen from the calculation results that at nearly twice the roll resonance frequency, the roll response of the damaged ship measured in the

Damage Stability, Fig. 5 Effects of wave height on roll motion

model test appears the second natural frequency, which is analyzed to be caused by the sloshing of the tank.

Dead Ship Condition

Min Gu, Jiang Lu, Ke Zeng, Tianhua Wang,
Shuxia Bu and Jilong Chu
China Ship Scientific Research Center (CSSRC),
Wuxi, China

Synonyms

Resonance roll; Stability in beam sea and wind

Definition

Dead ship condition is one mode of stability failure. This scenario assumes that a ship has lost its power and has turned into beam seas, where it is rolling under the action of waves as well as heeling and drifting under the action of wind. (SDC 3/WP.5/Annex 6 [2016](#)).

Figure 1 shows the process by which dead ship stability failure develop. Firstly, the ship moves with drift-related heel under wind aerodynamic force and hydrodynamic reaction caused by transverse motion. Next, the ship encounters a sudden and long gust of wind. When the ship rolls at the

maximum windward angle, this is assumed to be the worst possible instant, action of wind is added to the action of waves. The strengthening wind increases drift velocity and this leads to an increase of the hydrodynamic drift reaction. The increase of the hydrodynamic reaction leads to the increase of the heeling moment. The gust is assumed to last long enough so the ship can roll to the other side completely. If the leeward roll angle is too large, or some openings may be flooded, the stability of the ship is considered insufficient (SDC 3/WP.5/Annex 6 [2016](#)).

Historical Development

Dead ship condition is the first mode of stability failure addressed with physics-based severe wind-and-roll criterion, also known as the “weather criterion,” which is adopted by IMO in 1985 (Res. A.562(14)) and is now embodied in section 2.3 of the 2008 IS Code, Part A. (Belenky et al. [2011](#)).

The severe wind and rolling criterion (weather criterion) is one of general provisions of the 2008 IS Code. This criterion was originally developed to guarantee the safety against capsizing for a ship losing all propulsive and steering power in severe wind and waves, which is known as a dead ship. Because of the forward velocity of ships is zero, this assumes an irregular beam wind and wave condition. Thus, operational aspects of stability are excluded in this criterion (IMO, MSC.1/Circ.1281 [2008a](#)).

The weather criterion firstly appeared in the IMO instruments as Attachment No.3 to the Final Act of Torremolinos International Convention for the Safety of Fishing Vessels, 1977. During the discussion for developing the Torremolinos Convention, the limitation of the GZ curve criterion based on resolution A.168 was remarked; it is based on experiences of fishing vessels only in limited water areas and it has no way for extending its applicability to other ship types and other weather conditions. Thus, other than the GZ curve criterion, the Torremolinos Convention adopted the severe wind and rolling criterion including a guideline of calculation.

Dead Ship Condition, Fig. 1 Scenario of stability failure in dead ship conditions (Belenky et al. 2011; SDC 3/WP.5/Annex 5 2016)

Because of the limitation of statistical data source of GZ curve criterion for passenger and cargo ships in resolution A.167, the discussion was raised at IMCO. As a result, a weather criterion was adopted also for passenger and cargo ships as well as fishing vessels of 45 m in length or over, as given in resolution A.562(14) in 1985. This new criterion keeps the framework of the Japanese stability standard for passenger ships but includes USSR's calculation formula for roll angle. For smaller fishing vessels, resolution A.685(17) was passed in 1991. Here the reduction of wind velocity near sea surface is introduced reflecting USSR's standard. When the IS Code

was established as resolution A.749(18) in 1993, all the above provisions were superseded.

In 2001 (IMO 2001a), following a submission from Italian delegation (IMO 2001b) arguing the methodology adopted to calculate several parameters of weather criterion, the IMO SLF Sub-Committee was tasked to start the revision of the Intact Stability Code as contained in Res. A.749. The working group operating in the frame of the SLF Sub-Committee was concentrated on polishing and restructuring Res. A.749 to make Part A of the Code mandatory, under SOLAS and ILLC Conventions, as requested by German delegation. This part was completed in 2007 with

adoption of the new International Intact Stability Code 2008 (IMO 2008b). This transformation provides alternative ways to comply with weather criterion for ship typologies which previously could be managed at national level (Francescutto 2019).

The basic principle of the weather criteria in IS Code 2008 is energy balance between the beam wind heeling and righting moments with a roll motion taken into account, as shown in Fig. 2, the energy required for restoring is larger than that required for the wind heeling moment. Since no roll motion is taken into account, a ship is assumed to suddenly suffer a wind heeling moment at its upright condition.

As the statement “Criteria included in the Code are based on the best state-of-the-art concepts, available at the time they were developed, taking into account sound design and engineering principles and experience gained from operating ships,” the new intact stability criteria include five stability failure modes developed, except for dead ship condition, which include excessive acceleration, pure loss of stability, parametric rolling, and surf-riding/broaching. The main purpose of these criteria is to enable the use of the latest numerical simulation techniques for evaluating the safety level of a ship from an intact stability viewpoint (IMO, Msc.1/Circ.1627 2020); the criteria will be still with reasonably changes.

Experimental Method for Dead Ship Condition

For the experiment under dead ship condition, three mooring-fixed model methods are used widely in beam wave. Firstly, the model is drifting freely in beam seas with two protected ropes which could also avoid the ship escaping from the worst scenario due to yaw moment as shown in Fig. 3a. Secondly, the ship model is orthogonal to the wave direction during the test through a wire system in which four wires connected to the ship model at bow and the stern, respectively, where the height is set be equal to water surface as shown in Fig. 3b. In the second method the drift and yaw could be softly restrained by the counterweight and heave, pitch, roll, and sway could be free. Thirdly, the ship model is also kept to be orthogonal to the wave direction by a wire system, however, in which four wires with four short springs connected to the ship model at bow and the stern, respectively, where the height is set be equal to water surface as shown in Fig. 3c. In the third method, the other ends of the four wires are fixed steadily, so the drift could be restrained and sway, heave, pitch, and yaw could be softly restrained (Gu et al. 2015).

The above experimental methods just consider the ship model in beam wave. However, the wind is also a key factor, which needs the laboratory equipped with wind blower. For the experiment under dead ship condition in beam wave and

Dead Ship Condition,

Fig. 2 Energy balance method in weather criterion of IS Code 2008

(a) Drifting freely

(b) Wire system with weight

(c) Wire system with springs

Dead Ship Condition, Fig. 3 The experimental setup in beam wave

wind, the model is usually kept to be orthogonal to the wind and wave direction by a wire system, which softly restrains drift and yaw, as shown in Fig. 4. The wire system is connected to the ship model at bow and stern where the height is set to be equal to calm water surface based on measured hydrodynamic reaction force and moment in a captive model test of the subject ship. The mean

Dead Ship Condition, Fig. 4 Lateral views of experimental setup

Dead Ship Condition, Fig. 5 Measurement points for wind velocity

of fluid dynamic force in the sway direction is cancelled out by a counterweight. Waves can be generated by plunger-type wave makers. Fluctuating wind is generated by a wind blower in the wave direction. The wind velocity is directly measured with a hot wire anemometer, as shown in Fig. 5 (Umeda et al. 2014).

Numerical Method for Dead Ship Condition

For the motion of ship under dead ship condition, the roll is the most important part. When the ship moves into beam seas and wind with zero speed, the ship may encounter large amplitude roll motion.

Mathematical Model of Ship Motion Under Dead Ship Condition

1DOF Motion Equation

Considering dead ship condition, an uncoupled 1DOF roll mathematical model is widely used

for predicting ship motion. The mathematical model with stochastic wave excitation and wind moment taken into account is used as (1).

$$\ddot{\phi} + 2\mu\dot{\phi} + \beta\dot{\phi}|\dot{\phi}| + \frac{W}{I_{xx} + J_{xx}} GZ(\phi) = \frac{M_{wind}(t) + M_{wave}(t)}{I_{xx} + J_{xx}} \quad (1)$$

where ϕ : roll angle, μ : linear roll damping coefficient, β : quadratic roll damping coefficient, W : ship weight, I_{xx} : moment of inertia in roll, J_{xx} : added moment of inertia in roll, GZ : righting arm, $M_{wind}(t)$: wind induced moment consisting of the steady and fluctuating wind moment, and $M_{wave}(t)$: wave exciting moment of Froude-Krylov component. The dot denotes the differentiation with time (Gu et al. 2013).

The wind induced excitation moment can be calculated by following equation:

$$M_{wind}(t) = 0.5\rho_{air}C_m(U_w + U(t))^2A_LH_C \quad (2)$$

where ρ_{air} : air density, C_m : the aerodynamic drag coefficient, U_w : mean wind velocity, and $U(t)$: fluctuating wind velocity calculated by the Davenport spectrum. Furthermore, A_L : lateral windage area and H_C : the height of the center of the wind force from the center of the hydrodynamic reaction force.

The fluctuating wind velocity is calculated by following equation and Davenport spectrum is used.

$$U(t) = \sum_{i=1}^{N_w} b_i \sin(\omega_i t + \varphi_i) \quad (3)$$

$$b_i = \sqrt{2S_{wind}(\omega_i)\delta\omega}$$

$$S_v(\omega) = 4 \cdot K \cdot \frac{U_w^2}{\omega} X_D^2 (1 + X_D^2)^{-\frac{4}{3}}$$

where

$$K = 0.003, X_D = 600 \cdot \omega \cdot (\pi \cdot U_w)^{-1} \quad (4)$$

The wave exciting moment of Froude-Krylov component can be calculated by the following equation:

$$W_{wave}(t) = W \cdot GM \cdot \gamma \cdot \Theta(t) \quad (5)$$

where γ is the effective wave slope coefficient, and $\Theta(t)$ is a wave slope calculated by ITTC wave spectrum as follows:

$$\Theta(t) = \sum_{i=1}^{N_w} \frac{\omega_i^2}{g} a_i \sin(\omega_i t + \varphi_i) \quad (6)$$

$$a_i = \sqrt{2S_{wave}(\omega_i)\delta\omega}$$

$$S_{wave}(\omega_i) = \frac{A}{\omega_i^5} \exp\left[\frac{-B}{\omega_i^4}\right] \quad (7)$$

$$A = 172.75 \frac{H_{1/3}^2}{T_{01}^4}, B = \frac{691}{T_{01}^4}$$

where $H_{1/3}$ is the significant wave height and T_{01} is the mean wave period.

4DOF Motion Equation

1DOF model can obtain satisfied results in some wave condition, but other more accurate models are also used to simulate the motion under dead ship condition. If surge and yaw motion is constrained for realizing a beam sea condition in model experiments, sway, heave, roll, and pitch motions can be modeled as follows (Kubo et al. 2012):

$$m\ddot{x}_2 = F_2(x_2, x_3, x_4, x_5, \dot{x}_2, \dot{x}_3, \dot{x}_4, \dot{x}_5, \ddot{x}_2, \ddot{x}_3, \ddot{x}_4, \ddot{x}_5, t)$$

$$m\ddot{x}_3 = F_3(x_2, x_3, x_4, x_5, \dot{x}_2, \dot{x}_3, \dot{x}_4, \dot{x}_5, \ddot{x}_2, \ddot{x}_3, \ddot{x}_4, \ddot{x}_5, t)$$

$$I_{44}\ddot{x}_4 = F_4(x_2, x_3, x_4, x_5, \dot{x}_2, \dot{x}_3, \dot{x}_4, \dot{x}_5, \ddot{x}_2, \ddot{x}_3, \ddot{x}_4, \ddot{x}_5, t)$$

$$I_{55}\ddot{x}_5 = F_5(x_2, x_3, x_4, x_5, \dot{x}_2, \dot{x}_3, \dot{x}_4, \dot{x}_5, \ddot{x}_2, \ddot{x}_3, \ddot{x}_4, \ddot{x}_5, t) \quad (8)$$

where the suffices 2, 3, 4, and 5 denote sway, heave, roll, and pitch motions. The ship mass is indicated by m and the moment of inertia due to i th ($i = 1, \dots, 6$) direction is I_{ii} . The external forces or moments in the i th direction, F_i , are assumed to consist of buoyancy (B), the Froude-Krylov (FK), radiation (R), diffraction (D), gravity (G), wind (WD), and hydrodynamic reaction (HR) components as follows:

$$F_i = F_i^B + F_i^{FK} + F_i^R + F_i^D + F_i^G + F_i^{WD} + F_i^{HR} \quad (9)$$

Additional Requirements

For the dead ship condition failure mode, IMO Interim guidelines on the second-generation intact stability criteria takes additional requirements for adequately predicting ship motions (IMO, Msc.1/Circ.1627 2020):

1. Ship motion simulations should include at least the following four degrees of freedom: sway, heave, roll, and pitch.
2. Three-component aerodynamic forces and moments generated on topside surfaces may be evaluated using model test results. CFD results may be admitted upon demonstration of sufficient agreement with a model experiment in terms of values of aerodynamic force and moments. Empirical data or formulae could be applied within their applicability range.

Technical Challenges

Rolling Damping

A ship may occur extreme roll motion in severe waves and winds condition, thus leading to large-amplitude roll motion. Large roll angles and accelerations can cause significant crew inefficiency and reduce the stability of the hull, or leading to capsizing. A sufficient roll damping moment prevents the dynamic loss of stability, and roll damping is also fundamental in case of dead ship failure mode addressed by second-generation intact stability criteria, thus the accurate prediction of roll damping of ships is particularly important.

At present, the estimation of roll damping is both challenging as well as an extensively studied problem. Usually, there are three methods to evaluate the roll damping: semiempirical approach, model test, and numerical simulation. The most popular semiempirical method is component-based method, which considers the physical processes of roll motion damping with various means of energy dissipation, including friction, lift, wave-making, and vortex

generation from the hull, as well as the influence of appendages (Ikeda et al. 1978; Himeno 1981). Unfortunately, the range of application is limited in most extreme roll motion. Different techniques of model test exist to estimate roll damping, which are roll decay motion, harmonic excited roll motion, and harmonic forced roll motion. Roll decay and harmonic excited roll based on roll angle measurements make the comparison of the roll damping coefficient between experiment and simulation difficult. Roll decay is fully nonstationary harmonic process, the initial state and higher Froude number have a strong influence on the test results. Considering the rudder is used to hold the model on course in harmonic excited roll motion, the propeller-rudder interaction adds the complexities for model test. The fixed roll axis of harmonic forced roll motion and the direct determination of the moment make it easier to measure roll period and amplitude.

Influence of the Deck Entering the Water

If a ship has lower freeboard for a substantial part of its length, the forces related to the entrance of the deck into the water may play a significant role in the dynamics of a ship. If the leeward side bulwark becomes submerged and a ship has significant lateral motion toward the immersed side, then a significant hydrodynamic reaction and corresponding additional heeling moment appear (Belenky and Sevastianov 2007).

There are two kinds of situation: water on deck and deck in water. Water trapped on deck (without an interface of the green water with the outside fluid domain) acts like a moving mass when the ship rolls, while the deck-in-water situation (where the water on deck and outside the hull can be considered as one fluid domain) leads to the development of hydrodynamic forces on the deck surfaces, which dominates the dynamics. These effects were studied since the late 1960s, and have been discussed previously at IMO (IMCO STAB/INF.27 1966) and in succeeding sessions.

The influence of the deck entering water leads to drastically different dynamics between high and low freeboard ships, under the action of a similar sudden gust of wind, see Fig. 6.

Dead Ship Condition, Fig. 6 Difference in response to a sudden wind gust

Synonyms

[Removal of fixed platform](#)

Definition

The decommission of a fixed platform is the final phase of its life cycle. The process starts by unplugging and abandoning the well; removing the conductors, subsea systems, and topsides followed by the installation process in reverse sequence; doing remediation work; and clearing debris from the project site. Modules can be removed and placed on barges and then towed to different locations depending on the planning for subsequent use. The usual methods of decommissioning are complete removal, partial

removal, and remote reefing (Ibrahim Khan and Islam 2007).

Scientific Fundamentals

Decommissioning Process

The decommissioning process of fixed platform is very complex, which can be divided into the following steps.

Planning and Engineering

The initial phase of decommissioning is to gather all the available information and prepare an Authorization for Expenditure (AFE) for owner approval. The structure is inspected, and an underwater survey may be performed. A lift analysis is developed by a structural engineer and reviewed by the project manager. Each well, pipeline, and platform requires permits for abandonment and removal which are prepared and submitted to the Bureau of Safety and Environmental Enforcement (BSEE) for approval and issuance before the work activities are performed. The project management group prepares a list of qualified contractors for each phase of the job, and the bid books are prepared and submitted to the owner for review and approval. Once approved, the contractors are sent a Request for Quotation (RFQ). Once received, the RFQs are reviewed by the project management team and recommendation for award sent to the platform owner for review and award of the work.

Well Plugging and Abandonment

After completing the preparation for decommissioning, it is time to start the on-site operation. Production wells that can no longer be used must be plugged to prevent the oil and gas reservoir fluids from migrating up hole over time and possibly contaminating other formations, fresh water aquifers, or the marine environment. A well is plugged by setting mechanical or cement plugs in the wellbore at specific lengths and intervals to prevent fluid flow. The main rig-less plugging process usually requires a spread containing the following: pump, cement blender, a combination wireline line unit, mud tank, and commonly

used materials such as cement, bridge plugs, and cutting equipment to conduct the operation. The plugging process can take from 7 to 10 days, depending on the number of wells on the structure, any issues in wellbore, and the service provider.

Pipelines Decommissioning

All pipelines connected to the platform are decommissioned. The decommissioning crew flushes the line by pumping a cleaning plug through the line with seawater. Divers or remotely operated vehicles (ROVs) will then expose the ends of the pipeline and cut the line above the riser bend and approximately 10 ft out from the base of the jacket. The riser bend is removed, and the cut end of the pipeline is plugged and buried 3 ft below the mudline. For the pipelines that run to shore, the line is cut just beyond the surf zone and plugged. The portion of the line that extends into the surf zone is removed to the beach line. The remaining line is plugged and buried.

Platform Preparation and Cleaning

Platform preparation includes the procedures associated with shutting down and preparing the facility for removal. Topside inspections and underwater inspections are generally conducted to determine the condition of the structure and to identify any problems for removal. Divers will perform the underwater inspection in water depths ranging from 0 to 200 ft, and ROVs will perform the underwater inspections from water depths ranging from 200 to 1200 ft. After the inspections have been completed, a crew paid on a day rate or fixed price bid prepares the structure for decommissioning after the wells have been permanently plugged and abandoned and the pipelines have been abandoned.

On the surface (topside of the platforms), the work includes the flushing/cleaning and degassing/purging of tanks, processing equipment and piping, disposal of residual hydrocarbons, removal of platform equipment, cutting of piping and cables between deck modules, separation of modules into individual units, installation of pad eyes for deck module lifting, removal of obstructions to lifting, and structural reinforcement.

Topside preparation also includes severing connections between the deck and jacket and verifying that all pipelines have had a section of pipe removed between the deck and jacket. Where permitted, marine growth can be removed from the structure at sea; otherwise it produces very foul odor during jacket disposal onshore.

Conductor Severing and Removal

The conductors can be removed prior to the HLV (heavy lift vessel) arrival or removed during platform decommissioning operations with the HLV. All conductors are severed and completely removed at least 15 ft below the mudline. The conductors can be severed by many methods, such as explosives, abrasive cutting, mechanical cutting, and diamond wire cutting.

Then casing jacks, platform crane, or the crane on an HLV can be used to pull the conductors. Regardless of the lifting device, the removal sequence is the same. The conductor is pulled upward until a 40-foot section is exposed. The conductor is cut using external mechanical cutters, or possibly the threaded connections are unscrewed. The cut section is then removed by the drilling rig or platform crane and placed on a workboat, barge or on the deck away from the work area. This procedure (pull, cut, and remove) is repeated until the entire conductor is removed. The jacks onboard may not be able to pull the combined weight if the conductor is grouted. In this case, a rig or crane is used until the jacks can pull the weight of the conductor by themselves.

Removing Topsides

Topsides consist of the deck and various modules. Its removal follows the installation process in reverse sequence. Each module is removed and placed on a barge. The module is secured by welding pieces of steel pipe (or plate) from the module to the deck of the barge. The deck section or support frames (cap trusses) are then removed by cutting the welded connections between the piles and the deck legs with oxygen-acetylene torches. All decks are removed in the same configuration as they were installed. Slings are attached to the deck/cap truss lifting eyes and to the HLV crane. The HLV's crane lifts the deck

sections from the jacket. The deck is then seated in the load spreaders and secured by welding steel pipe from the deck legs to the deck of the barge.

Substructure Removal

The substructure of fixed platforms can be roughly classified into jacket and concrete substructure.

Jacket Removal There are a few removal options including complete removal, partial removal, and remote reefing (Osmundsen and Tveterås 2003).

1. Complete removal

Complete removal of jacket begins with separating the structure from its foundation. After the legs and piles are cut and the diagonal braces removed, the jacket section is rigged, lifted, and sea-fastened on a barge. At times, the jacket is severed at multiple elevations because of its dimensions. The jacket is de-ballasted, picked up, towed to shallower water, set, cut in two (vertically), and removed in sections. This procedure is repeated until the jacket is completely removed and placed on barges. The structure is transported as a whole or in pieces to a scrap yard to be cut up and recycled.

2. Partial removal

This method suggests to remove only the top section of the jacket. The jacket's legs are severed as in complete removal, except that the cuts are made at the top portion of the jacket and the remaining part will be left in place. The remaining structure must not become a marine obstruction. The removed section of the jacket will either be transported to shore for disposal or reefed in place or at another approved reef location.

3. Remote reefing

Reefing may involve complete or partial removal of the jackets. The jackets are severed below the mudline (for complete removal) or at some partial depth (for partial removal) as described above. Structures may be reefed in place or at another approved location. If the jacket requires to be transported to an alternate

reef site, it will be de-ballasted as described in the complete removal method (Bull and Love 2019).

Concrete Substructure Removal There are three methods of concrete substructure removal:

1. Partial removal of the legs

After the deck and modules are removed, the upper part of the legs of the gravity base structures would be cut at the point of 55 m below sea level, in line with the International Maritime Organization (IMO) guidance. The rest of the structures would be left in situ on the seabed and documented in marine databases.

2. Leave in place

This method suggests the concrete substructures to be left wholly in place after the topsides being removed. As with partial removal, the location of the remaining structure will be marked and documented in marine databases and protected by a safety zone.

3. Complete removal

Complete removal of concrete substructure should follow a systematic procedure to avoid contamination and accidents. First, the integrity of the overall structure must be assessed. The drill cuttings accumulation on storage cells and the description of cell content should also be inspected. This operation can be carried out by an ROV (remotely operated vehicle) or AUV (autonomous underwater vehicle). Second, based on collected inspection results, remove the cuttings and store them in a barge. Third, remove the storage cell content. The oil storage cells are expected to be comprised of the following substances: attic oil, interphase material, water and sediment, etc. The last procedure is excavation of the concrete substructure foundation. The operation procedures of excavation is highlighted below:

Removing the conductors: The gravity platform structure is expected to be heavier than the original float-out, resulting from additions of conductors and sediments. Therefore, the removal of these conductors is necessary to reduce the weight. This will be done by a diver or ROV.

Sealing all penetration: A diver or ROV will seal all penetration areas to prevent the water from flooding into the structure during the refloating operation.

Installation of new control system: A new system would be required to monitor pressure in the cells, monitor and control the break out of the foundation, and monitor and control its draft and orientation during the tow to the shore. These systems are fitted onto various parts of the gravity platform using an ROV.

Ballast control system: All the water should be removed from the cells and legs using the hose fitted to an ROV to achieve the required buoyancy.

Equipment to break the under-base suction: The space between the foundation and the underlying seabed should be pressurized to move the foundation from the seabed.

Refloat and tow the foundation: As the water in the cells and leg is displaced by high-pressure air and sealed, a combination of buoyancy forces and under-base water pressure would lift the foundation from the seabed, and it will rise to the seabed. Once the structure is stable on the surface, it is towed near the shore site for the full dismantling process.

Disposal

The barge transports the whole topsides, including modules and deck, to a scrap yard. The modules may be lifted by cranes or skidded off the barge to the yard. Once the modules have been removed from the barge, the deck is skidded off the barge to the yard. All the structural components and modules are cut into small pieces and disposed of as scrap unless the deck will be reused. The production equipment is salvaged for reuse whenever possible.

Site Clearance and Verification

Following removal, the platform site and any location where the jacket is cut will be cleared of debris and verified that it has been cleared. Any trash that is retrieved from the sea floor is transported to shore for proper disposal.

Environmental Issues in Decommissioning

The main source of pollution in the decommissioning of platform is drill cuttings (the collective name for drilling mud, specialty chemicals, and fragments of reservoir rock) being deposited on the seafloor. It is clear that drill cuttings are a complex mixture which has an adverse impact on the environment. Each pile of drill cuttings represents a unique combination of sediment characteristics, contaminants, and benthic community, and each is affected by the local hydrodynamic regime. However, the constituents found in drill cuttings piles include heavy metals, specialty chemicals, organic contaminants, radioactive materials, and so on.

Available information on drill cuttings accumulations mainly focuses on three chemical groups, hydrocarbons, heavy metals, and to a lesser degree, radionuclides. Although there is uncertainty as to the extent to which oil concentrations reduce over time, it appears that most oil is dispersed during initial deposition. Thereafter, further degradation of oil in the pile will be very slow. In the case of drill cuttings piles, which contain potentially hazardous chemicals, synergistic effects from multiple contaminants should be considered. Dichloromethane extracted from sediments close to the platform are very toxic to Microtox, even after removal of sulfur. For the purposes of decommissioning, total amounts of wastes generation are required to be estimated. It helps to plan and develop appropriate measures during the decommissioning phase.

Key Applications

Decommissioning Regulations

1958 Geneva Convention on the Continental Shelf
This convention called for the complete removal of any installation that is abandoned or disused. It also outlines the responsibilities and duties of the states conducting oil and gas activities with regard to the continental shelf. Specifically, these activities are to be done in a way that does not interfere with the rights of other states. However, this convention does not contain specific regulations for

the methods of disposing of abandoned or disused structures.

1982 United Nations Convention on Law of the Sea (UNCLOS)

This international treaty on ocean governance came into force in 1994. Article 60(3) of this convention states:

Any installations or structures which are abandoned or disused shall be removed to ensure safety of navigation, taking into account any generally accepted international standards established in this regard by the competent international organization. Such removal shall also have due regard to fishing, the protection of the marine environment, and the rights and duties of other States. Appropriate publicity shall be given to the depth, position, and dimensions of any installations or structures not entirely removed.

This is to say that partial removal of marine structures may be permitted so long as the remaining structure does not have adverse effects on the natural environment, rights and duties of states, and navigational safety. This convention was the first to address the issue of sustainability with regard to disposal of offshore structures.

1989 Guidelines and Standards for the Removal of Offshore Structure (IMO)

These guidelines and standards specify that the decision to allow an offshore installation, structure, or parts thereof, to remain on the seabed should be based on a case-by-case evaluation. Matters to evaluate include, but are not limited to, potential effects on the marine environment, on navigation, or on other users of the sea and potential future effects relating to deterioration of materials.

The IMO guidelines and standards require monitoring of the accumulation and deterioration of material left on the seabed, to ensure there is no subsequent adverse impact on navigation, other uses of the sea, or the marine environment. This requirement is reflected in the EA by the requirement for a monitoring program at the site. Also among the standards in the IMO document is the requirement for the entire removal of abandoned or disused installations or structures standing in

less than 75 m of water and weighing less than 4000 t.

1992 Convention of the Protection of the Marine Environment of the North-East Atlantic (OSPAR) OSPAR is a regional treaty, only applicable in Europe, specifically to activities in the North Sea. The regulations for the decommissioning of offshore structures set by this convention are more stringent than the IMO guidelines (Hamzah 2003) and currently assume the complete removal of the structure and transport to shore for decommissioning, with limited allowances for alternatives (Ekins et al. 2006). Indeed, the OSPAR Decision 98/3 calls for:

- (i) The complete removal and onshore reuse, recycling, or disposal of all topsides and substructures or jackets weighing less than 10,000 t
- (ii) The complete removal of substructures weighing over 10,000 t, with the possibility to leave footings in place
- (iii) A consideration to derogate concrete gravity-based structures, floating concrete installations, and any concrete anchor base (ibid.)

Decommissioning Case

Brent Delta was one of the first platforms to be built in the very early days of Britain's oil and gas industry. It ceased production in 2011 after nearly 40 years of production. The topsides of Brent Delta was supported by a concrete GBS with three legs (two for drilling and one for utilities) that extend upward from the cluster of 19 concrete cells.

The Brent Delta topsides were removed and transported to the Able Seaton Port (ASP) facility at Teesside in 2017 after detailed technical and engineering studies, while its legs were left at sea. The SLV method was selected by Shell after analyzing several studies to determine the best method of removal the topsides (Fig. 1).

Plug and Abandonment of Wells

Before the topsides were removed, all of Brent Delta's 40 wells were plugged and made safe.

This program of work was performed in accordance with the "Oil and Gas UK Guidelines for the Suspension and Abandonment of Wells."

Removal of Conductors and Pipework

The topsides were linked to the GBS by pipework in the utility leg and by conductors in the two drilling legs. Most connections were severed at approximately 16 m above the height of the lowest astronomical tide (LAT), that is, slightly below the 19.8 m LAT height at which the concrete legs were cut. Other connections were cut at a lower level, but all were cut above the seabed.

Preparation for Lift

In order to ensure that the lifting beam of SLV contacted the topsides structure firmly and that topsides were strong enough to be lifted, eight lifting points were specially designed.

Cleaning of Topsides Process Facilities before Removal

The topside process systems were drained, purged, and vented, as appropriate, to ensure no pockets of hydrocarbon liquid or gas were present before the topsides were removed. Additional vents were created at selected locations in the topsides process system to ensure that they were not recharged from any trapped inventories, and drained systems were left open to the atmosphere to allow free-venting to occur so that gases did not build up.

Cutting the Legs

The topsides were fixed to the top of the legs by 5.5-m-long steel transition pieces located at +19.8 m LAT, just above the ring beam at the top of the concrete legs. In order to separate the topsides, a DWC machine was deployed inside the legs to cut through the grout and the bolts that secured the transition pieces to the ring beams (Fig. 2).

Removal of Attic Oil

When Brent Delta was in production, the 16 GBS cells were used to store oil prior to export. In preparation for CoP and subsequent decommissioning, the final amounts of crude oil

Decommissioning of Fixed Platform, Fig. 1 Brent Delta in 2013 (Shell UK 2018)

Decommissioning of Fixed Platform, Fig. 2 Using a diamond wire cutting machine on concrete legs (Shell UK 2018)

were exported from the cells and replaced by seawater. Because of the shape of the cell domes, however, and the configuration of the oil export line inside the domes of the Brent Delta cells, a small volume of crude oil and emulsion

remained trapped in the upper domes of the cells and could not be removed by the platform export system. This material, which amounts to about 50 m³ in each cell, is referred to as “attic oil.” It was removed to shore for treatment, recycling, or disposal as appropriate.

Lifting the Topsides

The Brent Delta topsides were lifted from the GBS as a single piece by the SLV Pioneering Spirit. Before finally committing to the operation, a detailed weather forecast was obtained by the Metocean engineer based on the vessel to determine whether the weather conditions would be within the design limits for the lift and a safe voyage to a predetermined safe harbor location afterward.

After completing pre-operational checks on the dynamic positioning (DP), ballast, and lift systems, the vessel was granted formal approval

Decommissioning of Fixed Platform, Fig. 3 Lift of the Brent Delta topsides (Brent Delta 2017)

from Shell and the Marine Warranty Surveyor to enter the 500 m safety zone and begin operations.

The vessel was accurately positioned so that the GBS legs fitted into the vessel's slot; the clearance between the vessel's hull and the platform substructure was sufficient to allow for some movement of the vessel. When all of the beams and yokes were in place, the SLV was progressively de-ballasted. Once the vessel was clear of the GBS legs, the hull connection beam was closed, and the vessel was ballasted to its transit draft, and all the X, Y, and Z drives of the lifting arms were placed into sea-fastening mode ready for transit (Fig. 3).

Decommissioning of Floating Platforms

Li Hongtao

Offshore Engineering Technology Center of
China Classification Society, Tianjin, China

Definition

When the floating platforms reach the end of their lives or the oil field is exhausted, the platforms will be decommissioned. For floating platforms, there are two main decommissioning options: direct dismantling and reuse. The dismantling process of floating platform includes the following steps: (1) platform removal preparation, (2) well plugging and abandonment, (3) pipeline and flowline decommissioning, (4) structure removal, and (5) site clearance and verification (Kaiser and Liu 2015).

Scientific Fundamentals

Basic Decommissioning Method

Different types of floating platform will lead to different disassembly schemes:

1. Decommissioning of semisubmersible platform

For semisubmersible platforms, the piles anchoring the structure to the seabed will remain in place, but the chains and cables will be removed. The upper chain sections will be removed with the HLV during hull removal. Cables will be removed with anchor handling vessels with twin wench spools. The risers can be removed with the HLV or pipelay barge. According to the hull's metric ton, two or more tow tugs are mobilized and rig to the hull. The platform is towed to an onshore facility capable of handling refurbishment or scrapping. The hull will be dismantled or refurbished onshore.

2. Decommissioning of floating production storage and offloading (FPSO) systems

The ultimate disposition of the FPSO will depend upon its condition at the end of the productive life and available options for further use. If the FPSO is decided to be dismantled, it will be towed from the site to a shipbreaking yard in accordance with international conventions. In abandonment, the production system will be isolated from the subsea wells. The production system will be flushed from the FPSO end using seawater to displace any residual oil and production fluids. The flushing water will be returned to the FPSO for treatment. Any residual hazardous waste will be taken to shore and treated at waste treatment facilities. Once the production system has been flushed and confirmed clean, the FPSO will be released from the mooring system for removal. The lines and chains from mooring system will be recovered. The steel suction piles will be abandoned in place. The topsides equipment will be removed and recovered offshore. The hull of FPSO will be towed to the dock.

3. Decommissioning of tension leg platform (TLP)

For tension leg platform, its mooring system consists of tendons and risers. The TLP is ballasted to slacken the tension leg tendons. These tendons will be dropped to the ocean floor and cut loose from anchorage with ROV. The tendons will be retrieved the tendons using an ROV and a dynamically positioned derrick barge. The de-ballasted buoyant hull can then be floated and towed to near shore for reuse or scrapping. For mini tension leg platforms, its hull can be floated or placed on a cargo barge and transported to near shore for reuse or scrapping.

4. Decommissioning of spar platform

There are a few decommissioning options including in situ disposal, dismantling in horizontal or vertical position, and artificial reefing.

(1) In situ disposal

The in situ disposal method suggests to sink the spar at the original working site. This is by far the simplest and cheapest option and also the safest since it would involve minimal exposure of the

workforce to hazardous operations. However, it leads to the releasing of the spar's contents into the marine environment and leaving a large obstruction on the seabed.

(2) *Dismantling in vertical position*

For this option, the platform needs to be towed to a sheltered deepwater area, partially decontaminated and cut into horizontal slices in vertical position. The slices will be transported ashore for final disposal. However, cutting in vertical position is difficult and dangerous to perform, exposing the workers to hazardous operations. If the hull loses control during cutting operation, the structure may sink and break up. Besides, the suitable deepwater area is hard to find.

(3) *Dismantling in horizontal position*

This method includes the steps of (1) removal of the topsides section, (2) repair of the damaged storage tanks, (3) rotating the hull to the horizontal position, (4) transferring the hull to a cargo barge, and (5) transporting the hull ashore for final disposal. The most critical step is to turn the spar from vertical to horizontal position, which is expected to take between 5 and 10 days to complete. This process begins with the installation of the valves, pumps, and pipelines of the reverse upending control system. Then the spar would be restricted by a pre-installed mooring system. The contaminated water in the storage tanks will be pumped into the tanker and replaced by an inert gas mixture of nitrogen and carbon dioxide. By ballasting and de-ballasting the tanks, the spar would be gradually tipped to the horizontal position. This operation should be done carefully to avoid exposing the tank walls to excessive stress which may lead to structure failure. The repaired tanks are still vulnerable and have to be orientated out of the water as much as possible.

(4) *Artificial reefing*

Artificial reefing is assessed as the simplest decommissioning option from the technical perspective. In the typical

procedure, topsides will be cleaned and removed. Explosive charges will be emplaced. And then tow the spar to the disposal site. The reefing process begins with releasing the tow lines and moving away the tugs. Finally the explosives are detonated by remote control.

Reuse Option

Compared to dismantling directly, redeploying the platforms to another field is economically much more attractive.

1. Reuse of TLP

In order to reuse the TLP, the tendon length should be adjusted, and the mooring system requires a reinstallation.

2. Reuse of semisubmersible platform

The reuse of the semisubmersible platform is similar to that of TLP. The platform needs to be towed to new waters, and the mooring system will be adjusted.

3. Reuse of FPSO

FPSO is easy to migrate from one domain to another. Generally, a FPSO will serve in 4–5 oil fields in its life. The anchors extended mooring or turret mooring systems can be picked up and reused in new oil field.

4. Reuse of spar platform

The major obstacle to the reuse of spar platform is that the long slender underwater column is hard to be towed around in vertical position. Therefore, the hull must be de-ballasted and rotated into horizontal position after the drilling and production deck being removed. Then the hull can be towed or transported by a giant cargo barge or semisubmersible. The anchor lines and sea floor anchoring system can be modified and reinstalled based on the requirements of the new location (MMS 2009).

Key Applications

Around 200 floating structures have been identified as scrapped globally since 2015 (NGO Shipbreaking platform 2019). In the following

section, a typical decommissioning case is presented.

Typical Decommissioning Cases

Red Hawk spar is the world's first cell spar platform with a 560-ft-deep hull consisting of seven giant cylinders. It ended life as the deepest floating production unit ever to be decommissioned in the Gulf of Mexico in 2014. After considering all available decommission options, it is decided to convert the hull into an artificial reef. This is the first spar ever to be reefed. The process is introduced below (Fig. 1).

1. Mooring disconnect

The mooring system of the spar consists of a windlass and an 800-ft-long work chain located on the topsides to service all six mooring legs. The work chain was cut in three pieces and paid out on three mooring legs, thus effectively lowering the tension in the entire mooring system. In addition, to remain

the storm safe during the topsides lift, the high capacity C-link connectors were used to connect the work chain segments to the top chains. Tugs were hooked up to provide station keeping while the mooring disconnect was completed.

2. Ballasting and de-ballasting

During ballast and de-ballast, the access to the spar is limited. Therefore, it needs a remote ballast/de-ballast system for all operations. The spar hull was 560 ft. long, 64 ft. in diameter and assembled with six outer cells connected to the center cell. Each cell had void tank at the top and variable ballast tank at the bottom. In this phase, the hull was ballasted so that the heavy lift vessel can hook up and lift the topsides. Then the hull was de-ballasted to reach a tow draft of 400 ft in order to be able to enter the 430-ft-deep reefing site (Fig. 2).

3. Towing and reefing

The towing route was pre-surveyed several months ahead of the tow to verify information obtained from public databases as well as to account for any seabed objects or anomalies. The pipeline crossings and collisions with other platforms should be avoided. It is also necessary to maintain adequate bottom depth clearances during the approach to the reefing site. With some convenient seas assisting from the stern, the tow lasted less than 2 days.

After arriving at the reefing site, the air from variable ballast tanks was vented in order to let more water in to lower the spar, until the spar was sitting firmly on the seabed in a vertical position. After that, crew was transferred to the spar to prepare the hull for the reefing operations. Once complete, all air valves for variable ballast tanks were left open and the crew transferred back to the derrick barge. One tug disconnected from the hull, and the other two pulled in the planned reefing direction until the hull began to free flood. The hull gradually pivoted around the bottom edge of the two cells and laid on the bottom in a horizontal position in less than 10 min. During the sinking, the tugs powered off and paid out work rigging, which were then disconnected from tow rigging with ROV assistance (Fig. 3).

Definition

Decommissioning of offshore oil and gas installations is generally regarded as a major challenge for the industry with technical difficulties, significant associated risks, and high costs. As the industry is beginning to gain some experience with some major installations in the North Sea being successfully removed and with over 100 facilities already decommissioned, it is becoming clear that the industry is on its way towards facing and meeting the challenges of decommissioning. This chapter discusses the main guiding principles of decommissioning and international laws and regulations relating to decommissioning which form the main obligations for countries and oil and gas operating companies. These regulatory obligations form the starting point for developing plans and processes for decommissioning together with engineering design and execution aspects. In the final analysis success depends on sound engineering to address technical solutions and select the most appropriate ones for implementation. The most appropriate solutions would be those that score well on the environmental front, safety, and cost. Experience to date is also described, with specific examples, noting achievements in terms of recycling of materials, safety record, and recent advances in industry capability.

Decommissioning Principles

The main principles of decommissioning of offshore installations are:

- Decommissioning should aim to achieve a clear sea bed (acknowledging that this will not always be achievable, given the technical complexities and risks involved).
- A “polluter pays” principle is adopted which means that we expect those who have benefited from exploitation of hydrocarbons to bear the responsibility for and cost of decommissioning.

International Regulations Relating to Decommissioning

The prime international regulations and guidelines relating to decommissioning are summarized below. It should be clarified that these regulations do not carry force of law as such but individual nations or regional lawmakers may enact such laws with reference to the international regulations. Many countries have enacted such laws. The most relevant international laws and conventions are:

1. OSPAR Convention and OSPAR Decision 98/3 (OSPAR 1998)
2. UN Convention on the Law of the Sea, 1982 (UNCLOS 1982)
3. IMO Regulations (IMO A.672 (16) 1989)
4. ISO Requirements (ISO 19901-6 2006; ISO 19901-9 2018)

OSPAR Convention

Under the OSPAR Convention for the Protection of the Marine Environment of the North-East Atlantic (OSPAR 1998) it is prohibited to dump disused offshore installations or leave them wholly or partly in place within the area covered by the convention. The decision specifying this (OSPAR Decision 98/3) recognizes that certain types of structures may be difficult to remove and it is therefore possible to apply for derogations from the general rule in specific cases. The sea area covered by this convention includes the North Sea, West of Shetlands, and parts of the Arctic.

Under Decision 98/3 it is required that: (1) the topsides of all installations must be returned to the shore; (2) all steel installations with a jacket

weight less than 10,000 tonnes in air must be completely removed for reuse, recycling, or final disposal on land.

The decision recognizes that there may be difficulty in removing the footings of large steel jackets (weighing more than 10,000 tonnes) and in removing concrete installations. Derogations will only be granted if there are significant reasons why an alternative disposal option is preferable to reuse or recycling, or disposal on land.

Because of the significance of the North Sea in offshore oil and gas activity, having more than 800 offshore installations in this sea area, the impact of OSPAR Decision 98/3 extends beyond the region and has global implications.

UN Convention on the Law of the Sea (UNCLOS 1982): Provisions on

Decommissioning

Article 60.3 of UNCLOS states that any installations or structures that are abandoned or disused shall be removed as necessary to ensure safety of navigation, taking account of any generally accepted international standards established in this regard by the competent international organization (the International Maritime Organization – IMO and International Standards Organization TC/67 Covering Offshore Oil and Gas Standards). Such removal shall have due regard to fishing, the protection of the marine environment, and the rights and duties of other states. Appropriate publicity shall be given to the depth, position, and dimensions of any installations or structures not entirely removed.

Furthermore, through Article 210 of UNCLOS member states are legally obliged to adopt laws and regulations to prevent, reduce, and control pollution of the marine environment by dumping, which must be no less effective than the global rules and standards. Article 210 also provides that such laws, regulations, and measures must ensure that dumping is not carried out without the permission of the competent authorities of States.

IMO Regulations Relating to Decommissioning

In October 1989, the IMO adopted guidelines and standards for the removal of offshore installations

and structures on a nation's continental shelf or its exclusive economic zone (Resolution A.672, IMO A.672 (16) 1989), in consultation with IMO member nations. The IMO guidelines and standards provide that, in general, an abandoned or disused offshore installation or structure on a continental shelf or an exclusive economic zone should be removed as soon as reasonably practical once it is no longer serving the prime purpose for which it was originally designated. The following standards should be taken into account when a decision is made regarding the removal of an offshore installation or structure:

- All abandoned or disused installations or structures standing in less than 75 m of water and weighing less than 4000 MT in air, excluding the deck and superstructure, should be designed to be removed.
- All abandoned or disused installations or structures emplaced on the seabed on or after 1 Jan 1998, standing in less than 100 m of water and weighing less than 4000 MT in air, excluding the deck and superstructure, should be entirely removed.
- Removal should be performed in such a way as to cause no significant adverse effects upon navigation or the marine environment.

Alternatively, the guidelines also provide guidance for leaving offshore installations wholly or partially in place if complete removal:

- is not technically feasible
- would involve extreme cost
- would involve an unacceptable risk to personnel or the marine environment

but should ensure in such cases that an unobstructed water column sufficient to ensure safety of navigation (and, in any event, of not less than 55 m) is maintained above the partially removed installation.

The IMO guidelines and standards which were designed essentially to ensure the safety of navigation make clear that they are not intended to preclude a coastal state from imposing more stringent removal requirements for existing or future

installations or structures on its continental shelf or in its exclusive economic zone.

ISO Requirements Relating to Decommissioning

ISO requirements for decommissioning appear primarily in 19901-9 Structural Integrity Management (ISO 19901-9 2018) and 19901-6 Marine Operations (ISO 19901-6 2006). These requirements are discussed and referenced further below under decommissioning activities.

Costs of Decommissioning

With about 6000 offshore installations worldwide and thousands of km of pipelines the costs of decommissioning may appear colossal. As example the cost of decommissioning Norway's 120 offshore installations (fixed platforms plus floating) plus 350 subsea systems has been estimated to be about US\$20 billion (Decommissioning of Offshore Installations 2011), while the projected cost of decommissioning of UK's 550 offshore installations has been estimated by UK Oil and Gas Authority (in 2018) to be about US\$75 billion. On this basis the total bill for decommissioning 6000 installations (many of them being steel well-head jackets which are relatively easier to remove than their North Sea counterparts) is likely to be of the order of US\$400 billion. These are staggering sums which are sometimes misunderstood leading some to conclude that these costs are prohibitively high. These are very large sums of money but when they are viewed within the context of the size of the oil and gas industry, they are not prohibitively high. When it is borne in mind that the decommissioning activity will be spread over a period of about 40 years, then an annual cost of US\$10 billion is not dramatic. Furthermore, to put things further in perspective this decommissioning cost is equivalent to the revenue from recoverable oil reserves of 10 billion barrels, at an average price of US\$40/barrel. The total recoverable reserves of the offshore oil and gas industry (produced and underway with the infrastructure already in place) are about 300 billion barrels of oil equivalent. On this basis the cost of decommissioning is equivalent to about

10 out of 300 or 3.3% of the sale value of oil and gas extracted. If further we take into consideration that the cost of decommissioning is incurred at the tail end of field life and use a discount rate of 5%/annum for the time value of money, then the cost of decommissioning is reduced further from 3.3% to about 2.5%. It should be recognized however, that another 50% or so of the sale value is used up in capital and operating expenditures. Hence if we consider a large project which leads to a sale revenue of US\$100 billion, then approx. US\$50 billion is used up as capital and operating expenditure, US\$3.3 billion in decommissioning, and the remaining US\$47 billion is "profit" which is shared between the government and the oil companies undertaking the investment, with the government share being about 60%. Thus provided that the companies involved and the governments make appropriate provisions, the cost of decommissioning is a relatively modest component of the total cost and is affordable.

Decommissioning Process and Main Activities

An overview of the decommissioning process is given below. A decommissioning plan needs to be developed during the design of the installations so as to ensure that a credible method of decommissioning has been considered and design provisions have been made where necessary. For instance, if the substructure is a concrete gravity base structure, which is very heavy and cannot be removed by lifting (e.g., Sakhalin Gravity Base Structures), then a method of re-floatation (e.g., by pumping air into certain compartments) needs to be developed and provisions made during construction.

The decommissioning process in general may consist of the following activities:

- Planning and engineering phase of decommissioning
- Well decommissioning and conductor removal
- Topside facilities decommissioning and removal
- Substructure decommissioning and removal
- Pipeline and subsea decommissioning.

Each of these activities is discussed further below.

Planning and Engineering Phase of Decommissioning

At the start of the planning phase field surveys are carried out to establish the status and condition of the installation. The data collected during the survey includes weights and center of gravity for platform modules in the topsides and for the substructure. Lifting points are identified and their integrity is verified. Locations where structural cuts may be needed for lifting are identified. Topsides equipment and piping is surveyed and assessed for cleaning and decontamination requirements to avoid pollution. Information is gathered on wells, drill cuttings, pipelines, risers, and all subsea equipment.

Engineering and design work is carried out to the level needed to allow selection of the preferred execution plan to verify that decommissioning and removal can be executed safely satisfying engineering and environmental standards. Removal should include site clearance procedures that comply with international and national regulations. Typically these regulations require removal of all components above the sea bed and piling removal to at least 5 metres below sea bed.

Components left above the sea floor (e.g., bottom sections of jackets, provided appropriate derogation has been obtained, suction piles, pipeline exchange manifolds, and subsea wellheads have been plugged and abandoned) are likely to require placement of navigational aids for shipping. This should form part of the decommissioning plan which will need to be submitted to the regulator for approval.

Well Decommissioning and Conductor Removal

Well decommissioning involves the plugging and abandonment of the well bores. This is one of the essential and primary stages of decommissioning. It consists of isolating productive zones of the well with cement, removing the production tubing and setting a surface cement plug in the well with the top of the plug a set distance below the sea

floor. In many cases it can be advantageous to plug and abandon wells as they become unproductive towards the end of field life so as to reduce the potential environmental and life safety exposure.

All components which span the water column, namely the conductor and parts of the casing strings, are cut at a suitable distance below mudline, and are removed prior to removal of the substructure.

Topside Facilities Decommissioning and Removal

Facilities decommissioning involves the flushing, cleaning, and removal of process equipment and facilities as well as the removal and environmentally sound disposal of waste streams.

The removal operations for topside facilities will in general utilize one of the following three methods:

- **Piece small dismantling:** The installation is dismantled offshore and cut into small sections which can be shipped onshore on barges or in containers.
- **Heavy lift:** Sub-assemblies like a complete module is lifted using a heavy-lift crane vessel following a sequence of reverse installation. The module is placed on a barge or on the crane vessel and transported to a decommissioning yard. Typical large offshore crane vessels are the **Thialf** and **Bolder** of Heerema or **Saipem 7000**. Owing to the heavy-lift vessel being the conventional method of installation and decommissioning of offshore platforms, a number of conventional lift vessels are available across the globe. This has also fostered a market with a healthy competition and competitive pricing. In naming convention, the following terms are commonly used to describe different lift vessels:
 - DB (Derrick barge or monohull crane vessel)
 - SSCV (Semi-submersible crane vessel)
 - SL (Sheerleg)
 - JU (Jack-up)

Decommissioning of Offshore Oil and Gas Installations, Fig. 1 Number of heavy-lift vessels grouped by lift capacity in tonnes

It is common to rate the capability of crane vessels by their maximum lifting capacity as illustrated in Fig. 1. Crane reach over the stern is also important, and also the station-keeping capability.

The jack-up lift barge is mainly designed for the offshore wind industry but could also be used for decommissioning projects.

- **Single Lift:** The entire topsides is removed in a single lift and transported onshore. If the topside weight is less than about 10,000 tonnes the above heavy-lift vessels may be used to carry out a single lift. A relatively new vessel constructed with decommissioning operations in mind is the **Pioneering Spirit** of AllSeas. This is a twin-hull vessel with a U-shaped slot at the bow which is 122 m long and 59 m wide. The width of the slot enables the vessel to embrace the platform within the slot and thereby lift the entire topsides up to a max weight of 48,000 tonnes, in a single lift using eight sets of specially designed horizontal lifting beams.

In 2017 the *Pioneering Spirit* executed a record-breaking operation with the 24,000 tonnes single-lift removal of Shell's iconic Brent D platform topsides in the North Sea as illustrated in Figs. 2, 3, and 4.

Substructure Decommissioning and Removal

Steel Substructures

Decommissioning of a **steel substructure** normally involves cutting of the foundation piles at a certain distance below sea bed. Local (national) regulations may have specific requirements regarding the minimum depth of removal below sea floor. Methods of cutting the steel piles below the sea floor (at a depth of typically 1 m below sea floor) are already available. The substructure may be then removed by lifting as a single piece, if it has a weight of less than 10,000 tonnes (in air). This is within the lifting capability of a large offshore crane vessel like the *Thialf* or *Saipem 7000*. If the weight exceeds this amount the substructure may need to be cut into two or more pieces and lifted using separate lifts. This picture is changing after 2016 due to the availability of the *Pioneering Spirit* which has capability to lift a steel jacket up to 20,000 tonnes in a single lift.

The complete list of options for steel substructures is similar to that of topsides, namely:

- Piece small dismantling
- Single or multiple lift using a heavy-lift vessel
- Single lift using *Pioneering Spirit*

D

Decommissioning of Offshore Oil and Gas Installations, Fig. 3 Beams connected to Brent D Deck, ready to start lifting by de-ballasting, April 2017

Decommissioning of Offshore Oil and Gas Installations, Fig. 4 Lifting of Brent D deck onto Pioneering Spirit completed, April 2017

Subject to national and regional regulations the substructure may be toppled in place to form an artificial reef or transported and placed at a designated reef site. Also the lower part of a steel jacket may be left in place as a reef if it is demonstrated that there is no practicable way to remove it and appropriate derogation is obtained, again subject to national or regional regulations. It is advisable to integrate structural decommissioning activities with the late-life structural integrity management plan for the platform, for instance inspections should be targeted to verify data (e.g., weights, CoG) and integrity information (e.g., for lifting points which will be used during removal) required for decommissioning activities.

Removal of large N Sea steel jackets: North-west Hutton was the first of the N Sea steel giants to be decommissioned. BP as operator examined the option of complete removal of the jacket by cutting into two pieces and concluded that this was not practicable. The company obtained derogation from UK government to leave the bottom third of the jacket including the footings and the drill cuttings in place. The top part of the jacket was removed by Heerema in 2009 using the Hermod HCV.

The **Murchison** steel substructure also in the Northern North Sea, operated by CNR International, was the second of the steel giants to be removed. The entire steel jacket was removed successfully in 2017 by Heerema using the Thialf heavy-lift vessel. The steel jacket with a total weight of 14,000 tonnes was cut horizontally below water and removed in two separate lifts.

Shell's Brent: A steel jacket with a total weight of 25,800 tonnes (excluding conductors) is among the heaviest in the North Sea and lies in a water depth of 140 m. The platform is supported by eight large footings (skirt piles) extending about 40 m above the sea bed. These are very difficult to remove. The company has carried out detailed assessments of removal options and has concluded that the top part of the jacket down to a depth of 84.5 m below sea level will be cut and removed, while the bottom part including the footings will be left in place (see Brent 2017), with a derogation similar to that for NW Hutton.

Concrete Substructures

Concrete substructures: Removal of heavy concrete gravity base structures is recognized to be extremely difficult and if possible it certainly carries significant risks. There are 18 such

installations in the North Sea including three in the Brent Field (Brent B, C, and D), Cormorant A, Dunlin, and 12 in Norway. The weight in air of each of these is in excess of 100,000 tonnes and hence is beyond the lifting capability of any vessel. Re-floating may be an option provided that the integrity of the compartments to be re-floated can be verified. During installation the base of the structure was often grouted to improve stability. The weight of this grout is large but it is unknown and cannot be removed. Recognizing the above challenges OSPAR regulations clearly allow for concrete substructures to be left in situ or be partially removed. If the part above sea water is removed it is required for the removal to be extended down to 55 m below sea level so as to ensure that the remaining part of the structure is not a shipping hazard.

Floating Substructures

The decommissioning of a floating system can be simply described as a reverse installation. Semi-submersibles, FPSOs, and TLPs can be removed by disconnecting the mooring lines and risers and towing the floating hull (with topsides) back to an onshore location for disposal. The topsides may be removed offshore by a crane vessel if that is considered preferable. For a spar the topsides need to be removed first (because they were installed last). The spar hull may be de-ballasted and placed horizontally onto a transport vessel (e.g., mighty servant) for transport to an onshore location.

An alternative to decommissioning is reuse in another field. Hence selling of the asset to an interested party for reuse is an option which has already happened on several occasions, especially with FPSOs (Fig. 5).

Pipeline and Subsea Decommissioning

A typical subsea infrastructure (see Fig. 6) may consist of several subsea wells connected via flowlines to a manifold and from the manifold connected to a floating or fixed platform via one or more flowlines. Export may be through a subsea pipeline. Additional subsea structures may include Pipeline End Manifold (PLEM), Umbilical Termination Assembly (UTA), Subsea Control Module, etc.

Given the variety of elements the decommissioning plan will involve many different activities. Here we generically address the decommissioning of (i) a subsea module, e.g., a well manifold and (ii) flowlines, pipelines.

Decommissioning of a Subsea Module, E.G., Well Manifold

Subsea structures need to be flushed clean so as to remove any remaining hydrocarbons before they are left in place or removed. In shallow water (e.g., less than 200 m) or areas subject to trawl fishing subsea structures are most likely to be removed so as to leave a clean sea bed. Structures in deeper water are candidates for decommissioning in situ. If the module is piled to the sea bed, the piles need to be cut first. Thereafter the module is lifted using a crane to a barge for transport to shore for further disposal.

Decommissioning of a Flowline or Pipeline

The flowline or pipeline decommissioning plan may depend on geographic location and/or national or regional regulations. Pipelines can be decommissioned and left in situ or completely removed. If the pipeline is already buried, the most likely decommissioning plan will involve disconnecting the pipeline from the platform, cleaning and plugging, and leaving it in place, ensuring that both ends are buried. The pipeline is normally filled with water before plugging. In the latest edition of UK Guidance Notes on Decommissioning it is stated that when pipelines, mattresses, and associated items are decommissioned in situ, it should be aimed to achieve a burial depth of 0.6 m to limit the risk that sea bed currents may expose the pipeline in the future. In some jurisdictions flexible pipe and umbilicals have to be removed from the seabed due to their plastic content.

Environmental Assessment

Consideration to environmental data collection for regulatory compliance and decommissioning option assessment should be given during the planning phase. Proper risk assessment should be carried out to screen all decommissioning

Decommissioning of Offshore Oil and Gas Installations, Fig. 5 Northwest Hutton Steel Jacket showing footings (skirt piles) top in place

options (options) to ensure the environmental implications of each are understood.

The environmental assessment method can vary, but in essence aims to identify the

environmental impacts of different options and enable a comparative assessment to be made to identify the most practically achievable option with the least environmental impact or

Decommissioning of Offshore Oil and Gas Installations, Fig. 6 Typical subsea infrastructure layout

maximize environmental benefit. Typically, once a specific option is agreed or as part of the assessment of options, a specific Environmental, Social, and Health Impact Assessment (ESHIA) will be required to support regulatory and company compliance. Relevant issues to consider typically include, but are not limited to:

- Physical impacts on the environment from removal of infrastructure
- Physical impacts or benefits on the environment from leaving infrastructure in place
- Potential emissions from platform operations and vessels during decommissioning
- Impacts from anchoring of vessels during decommissioning
- Potential disturbance to biodiversity or sensitive species (e.g., noise)
- Potential environmental impacts from residue or contamination of hazardous materials in installations
- Waste management and disposal, flush water handling, and potential for spills

- Biosecurity, accidentally transporting invasive species when moving between marine ecosystems
- Information, experiences, and base line data and from the operate phase of the asset to help scope and frame the ESHIA

More specific environmental risk management plans or procedures, such as waste management plans, biodiversity action plans, etc. may be required prior to implementation of decommissioning activities depending on the nature of the D&R project and the relevant regulatory regime; this will vary by project.

Social Performance

Some local stakeholders have lived with the local oil and gas operation from its construction and it is reasonable for them to expect to be engaged to understand the impact of decommissioning and get assurance that their needs should be considered. Other stakeholders, e.g., nongovernment

organizations with a stake in the process or the outcome need to be engaged so that their views can be heard. The social performance considerations include, but are not limited to, impacts of:

- Right of way or exclusion zones on livelihoods and fishery
- Residual impacts and safety risks from offshore installations decommissioned in place, e.g., impact on sea life and environment
- Opportunities from alternative use or reuse, such as local reefing, aquaculture, tourism, coastal protection, and local industrial area (onshore)
- Sustaining job opportunities, social investment, and local business development

An example where the need for engagement with a key stakeholder was not recognized in time and this had a decisive influence on the course of decommissioning is the Brent Spar. In 1995, Shell was embroiled in a public dispute over the decommissioning and disposal of the Brent Spar, a redundant oil storage installation in the North Sea. Brent Spar was a floating oil storage facility constructed in 1976 and moored approximately 2 km from the Brent Alpha platform. After evaluating a number of options for disposing of the spar, approval was sought by Shell/Exxon for deep sea disposal from the UK Government. Greenpeace became aware of the plan to sink the Brent Spar; the organization had been actively campaigning against ocean dumping in the North Sea since the early 1980s and lobbying for a comprehensive ban on ocean dumping through the OSPAR convention. Objections culminated in Greenpeace activists occupying the Brent Spar, an energetic international media campaign that ultimately influenced political and public opinion against Shell's preferred option. Brent Spar was internationally damaging to Shell's reputation: Despite the support of independent scientists for Shell's proposals, Shell did not win public acceptance. Use of emotional language against sea dumping and use of false information (by Greenpeace) regarding potential damage to the environment turned public opinion against Shell's decision for deep sea disposal of the Brent spar, towards a solution of onshore disposal

that is more damaging to the environment and much higher cost.

Industry Experience in Decommissioning

Industry experience is that the large concrete installations constructed over the period 1970–1985 are extremely difficult to be removed. They cannot be refloated safely and they cannot realistically be cut into pieces that can be liftable. This is recognized in OSPAR Decision 98/3. In Norway the government has granted exemptions from Decision 98/3 for two installations to be left in place. These are the Ekofisk tank and its protective concrete barrier and the concrete substructure of the Frigg TPC2 module.

On the other hand, experience with steel installations is that both substructure and topsides can be removed, brought onshore, and dismantled. The only exception is that the bottom part of very large steel jackets (notably NW Hutton and Brent Alpha in Northern North Sea), which includes large-diameter legs with grouted skirt piles, is very difficult to remove and some derogations have been granted to leave these in place. Recycling of structural steel rather than scrapping is the norm. In Norway alone the volume of steel recycling from decommissioning is about 80,000 tonnes of steel per year. Experience to date is that about 97% of recovered steel is recycled.

Overall the response of the industry to the challenges of decommissioning has been very positive with some significant improvements in capability (e.g., Pioneering Spirit, improvements in cutting technology). The experience accumulated over the last decade has been very valuable and would suggest that the offshore oil and gas industry will be successful in meeting the main objective of decommissioning which is to leave behind a clean seabed and clean environment.

Decommissioning of Subsea Facilities

Zunfeng Du and Haiming Zhu
Department of Naval Architecture and Ocean Engineering, School of Civil Engineering, Tianjin University, Tianjin, China

Definition

Decommissioning is a general term for a formal process to remove something from an active status. Decommissioning of subsea facilities refers to the safe abandonment of subsea production facilities and associated infrastructure (such as well-heads, pipelines, umbilicals, and so on) that are no longer operational.

Scientific Fundamental

Decommissioning Importance of Subsea Facilities

Decommissioning is a normal part of the offshore oil and gas lifecycle. Decommissioning of subsea

facilities is an action taken to fully consider the safety and environmental protection of workers after the expiration of the use of subsea facilities or for other reasons.

Subsea facilities are playing a very important role in the creation of cost-efficient field developments. As a means to tackle both new and existing exploration and production challenges, oil and gas projects commonly involve a subsea concept. Christmas tree, subsea oil gathering manifold, and underwater manifold center are the main facilities of the subsea production system. A range of technical decommissioning and disposal options exists for offshore facilities, each of which must be evaluated on a case-by-case basis. The scope of consideration should include a broad range of aspects and not only focus on the vicinity of the structure (Ibrahim Khan and Islam 2007; Kaiser 2017).

Decommissioning Options

Decommissioning options can include complete or partial removal, alternate use as well as leaving the infrastructure in situ (in place). The selected decommissioning option will consider all safety, social, environmental, technical, and economic aspects to provide the best balance of these factors. Decommissioning options will vary from facility to facility. Each facility and its associated infrastructure are made up of many components that require different methods to be considered.

- Complete removal, disposal onshore, or offshore
- Partial removal, disposal onshore, or offshore
- Abandonment in situ
- Alternate use, either within the oil and gas industry or other industries/purposes

Basic Work Before Decommissioning of Subsea Facilities

During decommissioning, some, if not all, of the subsea system will be removed and carried to shore for disposal. It is likely that the majority of the pipeline is recycled. There may be some residual pipeline contents that could not be removed through the flushing and cleaning procedures, including wax, scale, oily sludge, or NORMS (naturally occurring radioactive materials).

During project design, engineers should establish the methodology for both the bulk removal of hydrocarbons and cleaning the pipelines to the proposed cleanliness standards. The bulk removal procedure, possibly completed in parallel with the precommissioning procedure, would require calculated pigging and draining routes to transport the bulk hydrocarbons to shore for processing, whether that is through a trunk line or tankers. During the design phase, cleanliness verification procedures must be assessed, for example, sampling pipeline contents at topside until a specified cleanliness is reached or by removal of a section of the subsea pipeline for inner wall inspection.

Key Applications

Wellheads

Production wells that can no longer be used must be plugged to prevent the oil and gas reservoir fluids from migrating up hole over time and possibly contaminating other formations, fresh water aquifers, or the marine environment. A well is plugged by setting mechanical or cement plugs in the wellbore at specific lengths and intervals to prevent fluid flow. The main rigless plugging process usually requires a spread containing the following: pump, cement blender, a combination wireline/electric line unit, mud tank, and commonly used materials such as cement, bridge plugs, and cutting equipment to conduct the operation. The plugging process can take from 7 to 10 days, depending on the number of wells on the structure, any issues in wellbore, and the service provider (Vrålstad et al. 2019). The well plugging and abandonment techniques are listed in Table 1.

Rigid Pipelines

Rigid pipelines, if not buried or trenched, may have to be removed after Cessation of Production. Options for flushing and cleaning, making the pipeline safe and abandoning in situ, removal of structures and mattresses, etc. are established on a case-by-case decision and are usually based on engineering justifications and approval by the regulator. Generally, rigid pipelines are difficult to remove, especially the larger diameter

pipelines. Once a pipeline is buried beyond the mobile sediment layer, a minimum depth of approximately 0.6 m, it will likely remain buried after decommissioning. A recommendation is to bury the pipeline during installation to avoid costly removal in the future (Rouse et al. 2018). Pipeline abandonment techniques are listed in Table 2.

Umbilicals

Umbilicals are required to be removed unless they are buried and are proven that they will remain buried post-decommissioning. Decommissioning umbilicals creates problems that are similar to flexible flowlines, including flushing and cleaning, removal, and integrity checks. Hydraulic fluid and chemicals inside umbilicals must be cleaned out, with more stringent cleaning standards than trace hydrocarbons in pipelines. There may be issues with umbilical recovery, and an integrity assessment is recommended to determine the umbilical integrity at the end of life. The removal method and whether potential reuse is possible will depend on the integrity. Umbilical decommissioning techniques are listed in Table 3.

Pipeline Bundles

Experience on removal of pipeline bundles is limited. Similar issues need to be considered as for rigid pipelines – cleaning of each pipeline, removal procedure, can justification be made to leave in place, reuse potential, etc.

If a bundle consists of an umbilical and a pipeline, the bundle is generally considered one unit. However, if the pipeline is unburied and is to remain, a further assessment is recommended on the stability of the straps. If the straps are expected to corrode, the straps may have to be cut, and the umbilical removed to prevent any snagging hazards.

Flexible Flowlines

Flexible flowlines, due to their size and length, are typically recovered by re-reeling after the life of the field. Flushing and cleaning flexibles are challenging especially if they are not designed with a smooth bore. Smooth bore flexibles are easier for hydrocarbon removal during decommissioning

Decommissioning of Subsea Facilities, Table 1 Well plugging and abandonment techniques (ICF 2016)

Facility type	Characteristics	Abandonment technique
Fixed platform wells	Problem free wells on platform that can support P&A spread	Use a workboat and rigless abandonment
		If no platform crane or insufficient capacity, include a portable crane or casing jacks. Drilling rig, if present on the platform, is used in place of jacks
		Rig-up, perform diagnostics, and P&A the wells
Fixed platform wells	Problem free wells on platform that cannot support P&A spread	Use a liftboat and rigless abandonment
		If no platform crane or insufficient capacity, include a portable crane or casing jacks
		Rig-up, perform diagnostics and P&A the wells
Fixed platform wells	Problem wells on platform that can support P&A spread	Use a workboat and rigless abandonment
		Depending on well problem, the following spread(s) would be included
		Snubbing unit
		Coil tubing unit
		Hydraulic workover unit
		Drilling rig
		Milling tools
		If no platform crane or insufficient capacity, include a portable crane or casing jacks. Drilling rig, if present on the platform, is used in place of jacks
Fixed platform wells	Problem wells on platform that cannot support P&A spread	Rig-up, perform diagnostics, and P&A the wells
		Use a liftboat and rigless abandonment
		Depending on well problem, the following spread(s) would be included
		Snubbing unit
		Coil tubing unit
		Hydraulic workover unit
		Drilling rig
		Milling tools
Floating platform dry tree wells	Problem free wells	If no platform crane or insufficient capacity, include a portable crane or casing jacks. Drilling rig, if present on the platform, is used in place of jacks
		Rig-up, perform diagnostics, and P&A the wells
		Use a workboat, rigless abandonment, and casing jacks. Drilling rig, if present on the platform, is used in place of jacks
Floating platform dry tree wells	Problem wells	Depending on well problem, the following spread(s) would be included
		Snubbing unit
		Coil tubing unit
		Hydraulic workover unit
		Drilling rig
		Milling tools
		Rig-up, perform diagnostics, and P&A the wells
Subsea wells	Water depth <800 m?	Selection of work and vessel spreads depends on condition of well and water depth
	Non problem well or problem well?	Rig-up, perform diagnostics, and P&A the wells

(continued)

Decommissioning of Subsea Facilities, Table 1 (continued)

Facility type	Characteristics	Abandonment technique
Subsea wells	Divers or ROV?	Complete removal 15' bellow mud line
	Can well be plugged using rigless methods?	Remove tree and wellhead, unless waiver to leave wellhead is obtained
	Water depth >800 m	Selection of work and vessel spreads depends on condition of well and water depth
	Non problem well or problem well	Rig-up, perform diagnostics, and P&A the wells
	Divers and or ROV	Remove tree, obtain waiver to leave wellhead
	Can well be plugged using rigless methods?	

Decommissioning of Subsea Facilities, Table 2 Pipeline abandonment techniques (ICF 2016)

Facility type	Characteristics	Abandonment technique
Riser to riser	Diameter, length, product	Selection of work and vessel spreads depends on type of pipeline, whether fluids are flushed, depth of cover over the pipeline, and water depth Flushed clean, cut ends, remove a section from each end, plug, and bury Flush clean and remove pipeline in sections Flush clean and remove pipeline by reverse reeling
Riser to SSTI	Flushed fluids can or cannot be pumped down hole, through the pipeline or filtering equipment is or is not present on the receiving end	
SSTI to SSTI		

Decommissioning of Subsea Facilities, Table 3 Umbilical decommissioning techniques (ICF 2016)

Facility type	Characteristics	Abandonment technique
ALL	Diameter, length	Selection of work and vessel spreads depends on length, size, and purpose of umbilical and water depth
	Purpose – electrical or other	Flush clean non-electrical umbilicals
		Abandonment in place – the ends cut, plugged, and buried. Umbilicals are to be removed unless waiver is obtained to abandon in place
		Abandonment by removal – the ends cut, and umbilical is removed

than rough bore as hydrocarbons become trapped in the flowlines' rough inner wall and are unable to be cleaned. Besides, a rough bore, upon reeling, may spill trace hydrocarbons into the ocean and cause for a difficult onshore disposal for the trace hydrocarbons that remain trapped in the flexible flowlines' inner walls.

Stability Units/Concrete Mattresses

Mattresses are used for stability and protection on pipelines, valves, and subsea structures. They

withstand severe storms, and they are required to be removed during decommissioning if the structural integrity allows. Generally, any stability units that are placed on the seabed are to be removed during decommissioning. An additional complexity for underwater lifts is exacerbated by the uncertainty in weight and center of gravity of the unit/mattress. During design, heavier and stronger materials may be included to withstand more severe storms to ensure the mattresses remain intact for removal for decommissioning.

Subsea Valves

Valves and tees are useful pipeline components during decommissioning. Strategically placed valves could be used as an isolation point to remove a subsea structure while leaving the pipeline in place. For example, a subsea manifold with an elevation of 5 m on the seabed must be removed, while the buried flowlines connecting it to the riser base remained in situ. A subsea isolation valve was located 2 m away from the subsea manifold. Therefore, the logical cut point was directly upstream of the isolation valve and provided an end cap for the pipeline remaining in situ. After many years of use, the seabed valves may not provide a seal for decommissioning. Therefore, timely inspections and maintenance are important throughout the life cycle so the valve can maintain a seal at the end of the design life. The valve may require a design life for beyond the life of the field to ensure adequate performance after the Cessation of Production during decommissioning.

During decommissioning, valves should be ROV operated for ease. In many cases, operators choose diverless decommissioning methods to minimize the personnel safety risk. It is recommended that all valves are designed to be ROV operated to allow for a diverless decommissioning option, if applicable. The determining factor with diver assisted vs. ROV tasks is the access around valves and subsea structures. Debris removal by jetting, dredging, or mass flow excavation creates extremely low visibility and hinders the ROV's workability.

Manifolds and Other Subsea Structures

Subsea structures, including manifolds, jumper, and subsea tree, will require removal during decommissioning. During removal, actual weight of the structure will be unknown. Corrosion will decrease the unit weight by consumption of the sacrificial anodes, while spillage of grout, marine growth, and particle settling on the structure will increase it. The original pad eyes will remain on the structure, and ideally, they will be suitable to lift the structure with a crane. Break out loads can double the underwater weight of the manifolds. For ease in lifting, bigger and stronger pad eyes on

Decommissioning of Subsea Facilities, Table 4 Subsea structure decommissioning techniques (ICF 2016)

Facility type	Characteristics required	Abandonment technique
Manifolds	Lift weights and dimensions	Complete removal
	Water depth	Abandon in-place
PLET	Lift weights and dimensions	Complete removal
	Water depth	Abandon in-place
Jumper	Lift weights and dimensions	Complete removal
	Water depth	Abandon in-place
Subsea tree	Lift weights and dimensions	Complete removal
	Water depth	Abandon in-place
SUTA	Lift weights and dimensions	Complete removal
	Water depth	Abandon in-place

the template should be used to allow for extra weight uncertainty during removal (Table 4).

Deep Sea Mining

Xiangyang Li

China Ocean Mineral Resources R&D
Association (COMRA), Beijing, China

Synonyms

Deep seabed mining; Ocean mining

Definition

Deep sea mining is defined as the process of seabed mineral excavation, transmission, lifting from the deep to the surface, and extracting valuable metal elements or products from the minerals. The definition of deep seabed is usually distinct in different disciplines. Generally, the depth of deep seabed mining is referred to much deeper than 1000 m. Most of the seabed area deeper than 1000 m is located in the international seabed area which is under the regime of the International Seabed Authority (hereinafter referred to as ISA). In accordance with the regulations of ISA, any state or entity can submit and apply an exploration contract sponsored by the state or states (China Ocean Mineral Resources R&D Association 2015).

Scientific Fundamentals

Deep Seabed Mineral Resources

The amounts of deep seabed mineral resources are huge and usually include mineral resources such as polymetallic nodules, cobalt-rich crusts, polymetallic sulfides, deep seabed rare earths, and so on.

Deep seabed polymetallic nodules are usually found on the deep sea basins from 4,000 to 6,000 m. Due to the high manganese content, it is also commonly referred to as manganese nodules. In addition, polymetallic nodules are also rich in other elements such as copper, cobalt, nickel, and molybdenum. The rich-identified

polymetallic nodules in the international seabed (hereinafter referred to as the AREA) are located in the Clarion-Clipperton Fracture Zone in the Pacific Ocean. The estimated global resource for polymetallic nodules in the seabed is about 70 billion tons.

Cobalt-rich crusts means cobalt-rich iron/manganese (ferromanganese) hydroxide/oxide deposits formed from direct precipitation of minerals from seawater onto hard substrates containing minor but significant concentrations of cobalt, titanium, nickel, platinum, molybdenum, tellurium, and other metallic and rare earth elements. The cobalt-rich crust exploration contract areas are mainly located on the seamounts in the northwest Pacific Ocean. The estimated global resource for cobalt-rich crusts in the seabed is about 21 billion tons.

Polymetallic sulfides means hydrothermally formed deposits of sulfides and accompanying mineral resources in the seabed which contain concentrations of metals including, inter alia, copper, lead, zinc, gold, and silver. The contract areas of polymetallic sulfides in the AREA are located along the ridges of oceans, just like the Atlantic Ocean and India Ocean. The estimated global resource for polymetallic sulfides in the seabed is about 0.4 billion tons.

Deep Seabed Mining Technology (Hoagland et al. 2010; Wang 2015)

Broadly speaking, deep seabed mining technology includes submarine mineral excavation (cutting and/or collection), transmission and lifting, monitoring and control, surface support, mineral transportation, and subsequent mineral processing and metallurgy. In the narrow sense, deep seabed mining only involves the process of excavating seabed minerals to the surface ship.

With the development of deep sea technology and the gradual improvement of the understanding through deep sea mineral resource exploration, there have been successively proposed three prototypes of deep seabed mining, just as continuous linking buckets, pipeline lifting, and shuttle submarine type. Considering the factors such as mining scale and technical economy, it is

generally believed that pipeline lifting is the most promising type.

The whole deep seabed mining system is composed of the submarine (cutting) collection sub-system, the pipeline transmission and lifting sub-system, the monitoring and control sub-system, and the surface support sub-system.

The submarine (cutting) collection sub-system mainly removes and collects the seabed minerals into the mining vehicle by means of cutting, water jet, etc., and then crushes the collected minerals to adapt to subsequent pipeline transmission and lifting.

The pipeline transmission and lifting sub-system mainly uses the pumps to transport the minerals collected by the mining vehicle to the surface support vessel.

The monitoring and control sub-system mainly realizes the collection and comprehensive processing of positioning, navigation, and various operation information of the entire mining process, from underwater to surface, and realizes the smooth control of mining operation.

The surface support sub-system, also known as the deep seabed mining vessel, is the support platform for the whole mining operation and is the living platform for mining operators. The main functions include the launching and recovering of the underwater mining equipment, deep seabed mining operations, mineral onboard storage and transshipment, living facilities providing, etc.

Deep Seabed Mining Stages

Deep seabed mining activities usually include three stages: exploration, mining, and closure. The environment is an important factor in the mining process and is considered in parallel with all phases of mining.

Each stage of mining activities has different tasks. The exploration stage mainly includes prospecting, general exploration, detailed exploration, mining and metallurgical preparation, as well as environmental baseline survey and environmental impact assessment, and finally determining the mining areas. The focus is to get the inferred, indicated, measured resources and the probable, proved reserves according with the different exploration stages.

The mining phase mainly includes feasibility studies, mining system construction, mining operation, and environmental monitoring and assessment. The results of the feasibility study determine whether commercial mining is possible. If feasible, the mining system construction and specific mining work could be started. Feasibility studies include not only commercial and technical but also the feasibility of environmental monitoring and assessment. Mining may be terminated due to environmental issues.

If all goes well, it will enter the closure stage after the end of the mining. The closure stage is mainly the ecological rehabilitation, restoration, and evaluation.

Deep sea mining activities will be subject to the ISA Mining Code, which include regulations on prospecting and exploration for different resources and exploitation regulation in the process of formulation in accordance with the United Nations Convention on the Law of the Sea. Mining activities including the exploration and exploitation within the exclusive economic zone of a coastal State are subject to the domestic mining regulations of the coastal State. Mining activities in the international seabed area are not only subject to the exploitation regulations of the ISA but also to the relevant other international conventions and laws of the country in which the mining companies are registered.

Deep Seabed Mining Progress (Li 2017)

Up to 2018, the deep seabed mining activities generally are still in the exploration stage in the world. The ISA has formulated three regulations for the prospecting and exploration of polymetallic nodules, polymetallic sulfides, and cobalt-rich crusts in the AREA. The exploitation regulation of deep seabed mineral resources is still under drafting. Some coastal countries have issued the prospecting, exploration, and exploitation regulations for deep seabed mineral resources in the exclusive economic zone. At present, the ISA has approved 29 international seabed exploration contracts, including 17 exploration contracts for polymetallic nodules, 7 contracts for exploration of polymetallic sulfides, and 5 contracts for exploration of cobalt-rich crusts.

Although the first 15-year exploration contracts have finished for polymetallic nodules in 2016, there are still no contractors to start commercial exploitation. But many contractors have carried out different scales of deep seabed mining test including the USA, European Union, China, Japan, Korea, and some international companies. The mining activities in the exclusive economic zone go faster in comparison with the international seabed.

Commercial deep seabed mining has not yet become a reality mainly from the following challenges. First, the deep seabed mining must have a more competitive advantage before the similar ground resources become scarce and not only must be profitable but also have more comparatively advantages in cost, environmental impact, and so on. Second, it must be technically feasible, especially for commercial-scale mining technologies. Current existing mining technologies still require long-term testing during the mining operations. Third, the awareness from the environment is still insufficient. Too strict environmental regulations will make deep seabed mining work impossible. Certainly, if there is a necessary mineral only existing in the deep seabed, commercial deep seabed mining would soon be achieved, but this mineral has not yet been discovered.

Deep Submergence Rescue Vehicle (DSRV)

Yong Hu

Shanghai Jiaotong University, Shanghai, China
School of Transportation, Wuhan University of Technology, Wuhan, China

Synonyms

Submarine rescue vehicle (SRV)

Definition

A deep submergence rescue vehicle (DSRV) is a type of deep-submergence vehicle used for rescue of downed submarines and clandestine missions. While DSRV is the term most often used by the United States Navy, other nations prefer to call it submarine rescue vehicle (SRV). SRV is one type of submarine rescue submersible, which can carry submariners from a disable submarine to the surface. The function of submarine rescue vehicle is the same as submarine rescue bell. The typical difference between them is that the rescue bell is a bell shape submarine rescue system, the submarine rescue vehicle is a free move manned submersible. As a special manned occupied submersible, it consists of four major components: manned pressure hull, propellers system, observational system, and rescue system.

Scientific Fundamentals

Historical Development

Before 1970s, the McCann Rescue Chamber System remains in service in several contemporary navies, including the USN and the Turkish Navy. Submarine rescue philosophies evolved further in the 1960s following the loss of two American nuclear-powered submarines, US Ships Thresher, and Scorpion, despite both boats being lost in waters that precluded escape or rescue. After considering a variety of options, including

submarines with in-built escape pods and submarines with front ends that could be blown to the surface, the USN developed the deep submergence rescue vehicle (DSRV). Entering service during the 1970s the DSRV, a manned mini-sub that mates with a DISSUB's hatch and could carry 24 people at a time, offered great flexibility. With two built, one is maintained in an operational state so it can be flown in a C-5 cargo plane to a port nearest the DISSUB. It can then be placed onboard either a modified US or allied submarine. Operating from a submarine means that rough surface conditions or ice is less likely to adversely affect rescue operations (Fig. 1).

The deep submergence rescue vehicle (DSRV) was replaced with the submarine rescue and diving recompression system (SRDRS). The submarine rescue diving and recompression system (SRDRS) will be the Navy's twenty-first century submarine rescue system.

SRDRS will provide a new capability of pressurized transportation of rescuees from a stricken submarine directly to the decompression system eliminating the requirement for deep submergence rescue vehicles, mother submarines, and submarine rescue chambers. SRDRS is to include an air transportable rapid assessment/underwater work system, a decompression chamber system, and a pressurized rescue module. The SRDRS

will provide a global rapid response capability to support submarine rescue missions with an increase in capability at a fraction of the cost of the currently available systems.

The submarine rescue diving and recompression system (SRDRS) consists of four distinct elements, which include the assessment/underwater work system (AUWS); submarine decompression system (SDS); and the pressurized rescue module system (PRMS); and PRMS mission support equipment, including the launch and recovery system (LARS) a deck mounted A-frame crane used to launch and recover the PRM. The SDS, PRM, LARS, and associated generators and auxiliaries all compose the submarine rescue system (SRS). The submarine rescue diving and recompression system (SRDRS) consists of the submarine rescue system (SRS) in conjunction with the assessment/underwater work system (AUWS). These systems are designed to rapidly deploy to any location in the world via air and ground transportation and will be installed on a military or commercial vessel of opportunity (VOO). The SRS, approximately 183 tons, is installed aboard the VOO (Fig. 2).

As the world's leading submarine rescue service provider, James Fisher Defence and Divex (JFD) offers a world-class submarine rescue system capability, vital to the safety of submariners in the global defense industry.

Deep Submergence Rescue Vehicle (DSRV), Fig. 1 The US DSRV

**Deep Submergence
Rescue Vehicle (DSRV),
Fig. 2** The US PRMS

Deep Submergence Rescue Vehicle (DSRV), Fig. 3 LR5

The Royal Navy's LR5 submarine rescue vehicle (SRV) is similar to the DSRV in most aspects but instead of using a modified vessel the LR5 uses a ship of opportunity as the Mother Ship. The LR5 was replaced by the NATO submarine rescue service (NSRS), a system developed jointly by Britain, France, and Norway, while the USN is developing the submarine rescue diving and recompression system (SRDRS). Both systems are similar and will carry out rescue operations in three phases; reconnaissance, rescue, and crew decompression.

The Korean and Singapore navy also have LR5 SRV, manufactured by JFD (Fig. 3).

Russian deep submergence rescue vehicle AS-28 is a Priz-class deep-submergence rescue vehicle of the Russian Navy, which entered service in 1986. It was designed for submarine rescue operations by the Lazurit Design Bureau

in Nizhny Novgorod. It is 13.5 m (44 ft) long, 5.7 m (19 ft) high, and can operate up to a depth of 1,000 m (3,300 ft) (Fig. 4).

China began to research deep submergence rescue vehicle from 1971, named 7103 SRV. At that time, it was jointly developed by Harbin Engineering University, Shanghai Jiao Tong University, Huazhong University of Science and Technology, and Wuchang Shipyard. The boat was started construction at the Wuchang Shipyard in 1976 and was successfully tested in 1986. The boat is 14.88 m long, 2.6 m wide, 4 m high, with a displacement of about 30 tons and a speed of 4 knots. The working depth of 7103 SRV is about 300 m, and 22 crew members can be rescued at once time (Fig. 5).

In 2009, the Chinese Navy purchased the LR7 SRV from Perry Slinsby Systems Co. LR7 is an upgraded product from LR5 SRV. The LR7 SRV

Deep Submergence Rescue Vehicle (DSRV),

Fig. 4 Russian deep submergence rescue vehicle

Deep Submergence Rescue Vehicle (DSRV), Fig. 5 China 7103 SRV

has a total length of 25 ft (about 7.6 m) and a maximum working depth of 500 m. There are two pressurized manned cabin. The front cabin is the operation cabin; the rear cabin is rescue cabin. The LR7 SRV can carry out 18 rescuer at one time.

Compared with the US PRMS, the LR7 docking skirt cannot be rotated. LR7 SRV has a large angle adjustment ability by its angle adjustment system. LR7 SRV has a large spherical crown observation window, which gives the pilot a large visual range.

LR7 SRV was powered by zebra batteries. China has replaced the zebra batteries by lithium-ion batteries (Fig. 6).

Key Technology in the Development of a Deep Submergence Rescue Vehicle

The application of deep submergence rescue vehicle is a high-tech system engineering. In order to ensure the timely and effective completion of rescue operations, it is necessary to set up a strict operating procedure. How to travel to the disable submarine point and reach the crashed sea area in short time is not easy.

The main difficulties include: (1) The efficiency alarm system. The golden rescue time is only 72 h. (2) The internal environmental conditions of the disable submarine. The SRV must reach the disable submarine before the emergency

Deep Submergence Rescue Vehicle (DSRV), Fig. 6 China LR7

life support supplies are exhausted, or the toxic gas leaks in the submarine. (3) Efficient operating procedures. (4) The navigation ability of mother ship and SRV. It mainly includes the ability to search for the specific location of the disabled submarine and the position of the lifesaving platform. (5) Docking capabilities.

Technically, several aspects need to be considered. (1) The disabled submarine emergency life support system must be reliable and lasting. (2) The notification system should be established. (3) Improve operational efficiency and minimize the time for carrying and searching targets. (4) The docking process should be simple and reliable.

In the rescue operation, how to solve docking process is a big problem. How to adjust the docking angle of the SRV according to the disabled submarine's lifesaving platform position. How to observe the lifesaving platform when the visibility is zero and the current is very urgent. The movement of people will change the center of gravity of the entire SRV system and how to maintain the center of gravity system, how to evaluate the strength, and stability of a rotary skirt (if it is used). The interior space of the docking skirt is limited. It is not only used for

accommodating the wrecked submarine crew, but also used for installing the winch, pump, air sampling device, etc. The structure of the transfer skirt may be more complicated. How to achieve optimized design results in finite space to obtain the maximum available space. The maneuverability, terminal navigation ability, and docking skirt structure form determine the success of docking and rescuing. The two roles complement each other. The early deep submarine lifeboats required high handling performance due to the use of fixed docking skirts.

Development trend: The main components use the market products as much as possible. It is not only more reliable, but also can reduce the cost. The functions of SRV should be diversified and not limited to military use. SRV devices have special characteristics; they can also draw on the advantages of other submersible vehicles. With the technological advances in microelectronics, high speed digital computers, artificial intelligence, guidance and control hardware and software, automatic docking technology will gradually improve. The overall performance of SRV is expected to be greatly improved, and it can be developed in the direction of self-propelled manned submersible with cables. It is possible to

obtain reliable evaluation results through digital simulation and optimize the operating procedures through simulation to reduce the cost.

Definition

Deep tow system An underwater instrument system for comprehensive observation of deep-sea geology and geophysics, which is towed behind the mothership. Its main detection equipment is an underwater detection towed vehicle with depth and attitude adjustment ability. The equipment installed on the underwater towed vehicle includes a navigation and positioning system, side sonar, echo sounder, formation profiler, magnetometer, stereo camera, continuous temperature measurement device, sediment or biological sampler, and other detection instruments.

Scientific Fundamentals

The deep tow system is an undersea survey apparatus that is extensively used for ocean observation and ocean research. The system can perform high-resolution real-time online detection of seabed topography, shallow strata profiles, and physical and chemical parameters of seawater near the seabed. The deep tow system usually consists of an onboard control system, a towing cable, and a towed vehicle. Depending on different exploration purposes, different kinds of undersea detective sensing instruments could be installed in the towed vehicle. The operation of the deep tow system generally requires that the towed vehicle should have the ability to adjust its trajectory rapidly and stably in order to accomplish various kinds of high-speed mobility survey tasks. It can work continuously for a long time without energy limitation during operation. It is particularly suitable for long measuring line operation. However, the application of the deep tow system is a high-risk job, and the problems and challenges have been accompanied by the development of the acoustic deep tow system.

General Composition of Deep Tow System

The diagram of the underwater deep tow system is shown in Fig.1. The mothership is the loading

Deep Tow System, Fig. 1 Diagram of general deep tow system (Go and Ahn 2019)

platform of the deep tow system. The tow system is carried by the mothership to the operating site. After the planned task is completed, the deep tow system will be retrieved onto the mothership and be carried to the next operating site. At the same time, the control subsystem of the deep tow system is installed on the deck or some cabins of the mothership. The control subsystem provides the required electric energy for the towed vehicle and records and analyzes the detection data sent back from the towed vehicle. The towing cable connects the mothership and the towed vehicle. Since the deep tow system itself does not have the active movement ability, it must be towed by the mothership to realize underwater movement. In addition, the function of the towing cable also includes power transmission and communication links. According to different working depths, the length of the towing cable can be adjusted. In shallow water, it is about tens of meters. However, in the deep sea, the length will exceed 10,000 m. The towed vehicle is the core part of the deep tow system. The underwater detection function must be realized by the sensors installed in the towed vehicle. In order to provide a stable underwater attitude, the towed vehicle should have a certain adjustment ability.

Wang et al. (2017) present the Marine Controlled-Source Electromagnetic tow system,

as shown in Fig. 2. This tow system is divided into three parts, namely, the deck unit, the deep-tow cable, and deep-tow unit. Furthermore, the detailed design for each subsystem is given.

Tow Vehicle Control Method

The depth or trajectory of a towed vehicle can generally be controlled by changing its control surface deflection or by altering the length of the towing cable. Since the former control pattern has the ability of precise positioning and attitude control, it has widely been applied as a major control manner for underwater towed vehicles. Several typical types of this kind of underwater towed vehicle have been proposed. Among these, the towed vehicles named Flying Fish and Delta developed by the research group of Kuyshu University in Japan are quite representative (Koterayama et al. 1995; Nakamura et al. 2001). The trajectories of these towed vehicles are maneuvered by changing the deflection of control surfaces with certain control techniques, and underwater observation or sensing instruments are installed in a cylindrical fuselage. The depth of Flying Fish is mainly controlled by altering the deflection of the vehicle's principal horizontal control surface; while in the towed vehicle Delta

Deep Tow System, Fig. 2 Diagram of the Marine Controlled-Source Electromagnetic tow system (Wang et al. 2017)

the control surface is rigidly mounted, the depth of the towed vehicle is maneuvered by shifting a trim weight inside the vehicle to adjust the attack angle of its control surface. Furthermore, two thrusters are utilized at the stern of the Delta to generate a trim moment for a rapid depth change. Several other towed vehicles with a similar control way have also been proposed such as the towed vehicles Aurora, Towed torpedo, and Batfish as described in Buckham et al. (2003), Latorre and Mims (2000), and Dessureault (1976).

Analysis of Deep Tow System Motion

An accurate analysis of deep tow system motion is highly desirable for development and operational purposes. Reliable hydrodynamic force modeling is an essential part of an accurate prediction of tow

system motion. Kim and Choi (2007) and Zhang et al. (2010) start from a simplified version of hydrodynamic force model equations based on engineering intuition or empiricism. This kind of pre-simplification can accelerate the determination of hydrodynamic force modeling, but it could bring in an unexpected error in the expression of the nonlinear hydrodynamic model. Many studies have been aimed toward analyzing the cable and the tow-fish system (Chapman 1984; Grosenbaugh 2007). In these previous studies, the research effort was more focused on the global motion of the cable rather than on the detailed prediction of the tow-fish motion. The tow-fish was modeled either as a particle mass or as a simplified version of a rigid-body. Go and Ahn (2019) present a simulation-based methodology to determine hydrodynamic derivatives for the tow-fish, as shown in Fig. 3. Based on the actual

Deep Tow System, Fig. 3 Inertial and body-fixed coordinate systems of the tow-fish (Go and Ahn 2019)

operating conditions of the tow-fish, 32 simulation cases were set up and subsequently simulated using a CFD tool. A least-squares procedure was applied to determine the complete set of hydrodynamic damping coefficients. The forces and moments obtained from the CFD simulation were successfully reproduced by the second-order modulus expansion and the optimal hydrodynamic derivatives in the least-squares sense. The determined hydrodynamic derivatives were applied to the actual prediction of the tow-fish motion.

Design Method of Towed Vehicle

Towed vehicle design is the core part of the deep tow system development process. The key technologies of the towed vehicle design mainly include towing system design technology, acoustic detection technology, and system integration technology.

Tow System Design Technology. The tow system is a platform for various equipment installed on it. The design method of the tow system is also particularly critical in the deep-sea acoustic tow system. Moreove, the micro-

topography detection system also puts forward high requirements on the towed body. In summary, the technology contains the following points, towed vehicle hydrodynamic design technology, towed vehicle performance prediction technology, installation structure design technology, and deployment and recycling technology.

Micro-Topography Detection Technology. In the deep-sea acoustic tow system, micro-topography is the most important detection element of the system. The detection of micro-topography here mainly needs to obtain high-resolution topographic maps of the seabed, side-scan maps (seabed backscattered sound intensity maps), and shallow formation profiles. In summary, the technology includes the following points, micro-landform detection sonar design technology, sonar array design technology, and data fusion and post-processing technology

System Integration Technology. There is a variety of equipment installed on the towed vehicle. Optimizing the performance of the system, making the equipment work together, and reducing the mutual influence between the equipments is the main task of system integration. In summary, the technology includes the following points, technical index distribution technology,

power supply and communication technology, acoustic compatibility technology, towed body positioning technology, software system integration, and underwater safety assurance technology.

Key Applications

Wu et al. (2005) describe an alternative type of controllable underwater towed system. The towed vehicle in the system is composed of an adjustable depressing wing and a wing-shaped main body. The depressing wing serves as an actuator for the towed vehicle submerged depth control and the wing-shaped main body assists to produce an additional downward lift force to counteract the drag force on a towed cable and provides a large damping moment of pitching for the vehicle when it is towed at a certain velocity. It is expected that with such a design the objective of a rapid trajectory manipulation and a relatively stable attitude towing for the towed vehicle during a surveying operation can be obtained. The towed vehicle discussed in the research is a prototype intended to apply in field underwater survey towing (Fig. 4).

Considering the specifics of the deep-water environment, a deep tow system has been developed, named Marine Controlled-Source Electro-magnetic Method (MCSEM) transmitter system as shown in Fig. 5, which incorporates the high-voltage and long-distance power supply, high-speed bidirectional communication data transfer between the deck unit and the towed body, intelligent control, high-power current pulse inverter, and precise time synchronization between transmitter and receiver. They have described the “real-time control technology of hardware parallelism” of the MCSEM transmitter. A gas hydrate exploration test was carried out in 2014 to verify the performance of the transmitter system. It can be used for gas hydrate exploration as an effective source. The advantages of the tow system are mainly reflected in the stable reliability and real-time response. In the future development of the MCSEM transmitter system, the technical index of the system will be continuously

Deep Tow System, Fig. 4 Schematic drawing of the towed vehicle; 1 main body, 2 luminous diode, 3 end plate, 4 towing ring, 5 depressing wing, 6 buoyancy chamber, 7 wing end plate, 8 thruster. (Wu et al. 2005)

improved so that it can perform better in marine resource exploration.

With the improvement of underwater transducers, there is a need for stable towing platforms for oceanographic measurements. The operational concerns result in a wide range of requirements. These performance requirements are often interconnected, which makes the design of a stable tow body a challenging work. Latorre and Mims (2000) describe the development of these performance requirements, along with the subsequent design, manufacture, and deployment of a 260 kg, $1.83 \times 1.06 \times 0.81$ m tow body. The project was completed in seven steps. With the completion of fabrication and flotation installation, the stable tow body was successfully towed

Deep Tow System, Fig. 5 Deployment of the deep-tow MCSEM transmitter (left) and the MCSEM receiver (right). The transmission current waveform and the

received signals were sampled at 150 Hz rate. The tail unit and transmission antenna were installed adjacent to the scheduled station. (Wang et al. 2017)

off Biloxi, Mississippi using the research vessel Tommy Murro (Fig. 6).

In 2008, the research team of the Institute of Acoustics of the Chinese Academy of Sciences, with the support of the China Oceanic

Association, started the upgrade of the DTA-4000 (as shown in Fig. 7, left) acoustic deep towing system. First, it upgraded the working depth to 6000 meters, and then gradually installed shallow profile sonar, DVL, and other equipments

Deep Tow System, Fig. 7 Deep tow system developed in the Institute of Acoustics, Chinese Academy of Sciences, DTA-4000 (left), DTA-6000 (right). (Liu et al. 2015)

Deep Tow System, Fig. 8 Ifremer near-bottom seismic system (Marsset et al. 2010)

to the DTA-6000 acoustic deep towing system (as shown in Fig. 7, right), which makes the deep tow system applicable to multiple ships and enhances the function and stability of the system software. During the upgrade and application, from 25 to 27 March 2011, with the scientific research ship Ocean I in the sulfide zone of the Mid-Atlantic Ridge, the DTA-6000 acoustic deep towing system completed three effective survey operations. The length of the dragging survey line is 30 km. In 2013, the DTA-6000 deep tow system successfully completed two 54.6-km detection missions in Haishan along with the scientific

research ship Ocean VI. For the first time, the micro-topography and shallow stratigraphic profile data were simultaneously obtained in Caiwei Haishan Mountain. In 2014, the deep tow system undertook the search task of Malaysia Airlines' missing passenger plane, with a search and rescue route of 34 km. (Liu et al. 2015).

The deep-towed seismic project is part of a more general project aiming at a deep-towed multisensor platform including a side-scan sonar, a magnetometer, and a sub-bottom profiler, as shown in Fig. 8. A neutrally buoyant towed fish behind a heavy depressor was chosen for the

future project to protect the imagery sensors from heave transmitted through the towing cable. (Marsset et al. 2010).

[DART; Deep-ocean Assessment and Reporting of Tsunamis](#)

Definition

The full name of DART buoy is Deep-ocean Assessment and Reporting of Tsunamis buoy, which is an enhanced tsunami warning system. The DART buoys are used to confirm the existence of tsunami waves generated by undersea earthquakes. These buoys observe and record changes in sea level out in the deep ocean. This enhances the capability for early detection and real-time reporting of tsunamis before they reach land.

To ensure early detection of tsunamis and to acquire data critical to real-time forecasts, the National Oceanic and Atmospheric Administration (NOAA) has placed Deep-ocean Assessment and Reporting of Tsunami (DART) stations at sites in regions with a history of generating destructive tsunamis. NOAA completed the original 6-buoy operational array (map of original six stations) in 2001 and expanded to a full network of 39 stations in March, 2008 (Zhao et al. 2013).

Originally developed by NOAA, as part of the U.S. National Tsunami Hazard Mitigation Program (NTHMP), the DART Project was an effort to maintain and improve the capability for the early detection and real-time reporting of tsunamis in the open ocean. DART presently constitutes a critical element of the NOAA Tsunami Program. The Tsunami Program is part of a cooperative effort to save lives and protect property through hazard assessment, warning guidance, mitigation, research capabilities, and international coordination. NOAA's National Weather Service (NWS) is responsible for the overall execution of the Tsunami Program. This includes operation of the U.S. Tsunami Warning Centers (TWC) as well as leadership of the National Tsunami Hazard Mitigation Program. It also includes the acquisition, operations, and maintenance of observation systems required in support of tsunami warning such as DART, local seismic networks, coastal, and coastal flooding detectors. NWS also supports observations and data management through the National Data Buoy Center (NDBC) (2018).

Scientific Fundamentals

Working Mechanism

DART systems consist of an anchored seafloor bottom pressure recorder (BPR) or so-called tsunameter and a companion moored surface buoy for real-time communications (Gonzalez et al. 1998). An acoustic link transmits data from the BPR on the seafloor to the surface buoy. The schematic diagram of DART system is shown in Fig. 1 (DART[®] 1998).

The BPR collects temperature and pressure at 15 s intervals. The pressure values are corrected

for temperature effects and the pressure converted to an estimated sea-surface height (height of the ocean surface above the seafloor) by using a constant 670 mm/psia. The system has two data reporting modes, standard and event. The system operates routinely in standard mode, in which four spot values (of the 15-s data) at 15-min intervals of the estimated sea surface height are reported at scheduled transmission times. When the internal detection software (Mofjeld) identifies an event, the system ceases standard mode reporting and begins event mode transmissions. In event mode, 15 s values are transmitted during the initial few minutes, followed by 1-min averages. Event mode messages also contain the time of the initial occurrence of the event. The system returns to standard transmission after 4 h of 1-min real-time transmissions if no further events are detected (DART[®] 1998).

Generations

The first-generation DART (DART I) systems had one-way communications from the BPR to the Tsunami Warning Centers (TWC) and NDBC via the western Geostationary Operational Environmental Satellite (GOES West) (Milburn et al. 1996). DART I became operational in 2003. NDBC replaced all DART I systems with the second-generation DART systems (DART II) in early 2008. DART I transmits standard mode data once an hour (four estimated sea-level height observations at 15-min intervals) (Milburn et al. 1996).

DART II became operational in 2005 (Green 2006). A significant capability of DART II is the two-way communications between the BPR and the TWCs/NDBC using the Iridium commercial satellite communications system (Meinig et al. 2005). The website for the DART data is supported by the National Data Buoy Center. A context diagram showing a DART II system and the related telecommunication nodes is shown in Fig. 2. It is clearly shown that the DART II system inside the dashed lines consists of two physical components: a tsunameter on the ocean floor and a surface buoy with satellite telecommunication capability. The two-way communications allow the TWCs to set stations in event mode in anticipation of possible tsunamis or

Deep-Ocean Assessment and Reporting of Tsunamis (DART) BUOY, Fig. 1 The DART II tsunami buoy system (DART® 1998). (Courtesy of NOAA)

retrieve the high-resolution (15-s intervals) data in 1-h blocks for detailed analysis. DART II systems transmit standard mode data, containing 24 estimated sea-level height observations at 15-min intervals, once every 6 h. The two-way communications allow for real-time troubleshooting and diagnostics of the systems. The DART buoys have two independent and redundant communications systems. NDBC distributes the data from both transmitters under separate transmitter identifiers. NDBC receives the data from the DART II systems, formats the data into bulletins grouped by ocean basin, and then delivers them to the National Weather Service Telecommunications Gateway (NWSTG) that then distributes the data

in real-time to the TWCs via NWS communications and nationally and internationally via the Global Telecommunications System (NDBC 2018).

DART II Buoy System Components

From the above, we can see that the DART II buoy system, which incorporates the latest technologies and advances, has longer maintenance intervals, and feature two-way communication. The DART II Buoy System consists of two physical components: a tsunameter on the ocean floor and a surface buoy with satellite telecommunications capability. Here we will introduce the two components in DART II.

Deep-Ocean Assessment and Reporting of Tsunamis (DART) BUOY, Fig. 2 Context diagram showing a DART II system and the related telecommunication nodes (Meinig et al. 2005)

Tsunameter

The block diagram in Fig. 3 shows how the components of a tsunameter function together (Meinig et al. 2005). The computer reads pressure readings, runs a tsunami detection algorithm, and sends and receives commands and data to and from the buoy via an acoustic modem.

Pressure Sensor The DART II pressure sensor is a 0–10,000 psi model 410K Digiquartz unit manufactured by Paroscientific, Inc. The transducers use a very thin quartz crystal beam, electrically induced to vibrate at its lowest resonant mode. The oscillator is attached to a Bourdon tube that is open on one end to the ocean environment. The pressure sensor outputs two frequency-modulated square waves, proportional to the ambient pressure and temperature. The

temperature data is used to compensate for the thermal effects on the pressure-sensing element (Eble and Gonzalez 1991).

Reciprocal Counter The high resolution precision reciprocal counting circuit continuously measures the pressure and temperature signals simultaneously, integrating them over the entire sampling window, nominally set to 15 sec. There is no dead period between the sampling windows. The circuit has a sub-millimeter pressure and sub-millidegree temperature least-count resolution. The reference frequency for the reciprocal counter is derived from a low power, very stable, 2.097152 MHz, temperature-compensated crystal oscillator. A real-time calendar-clock in the computer also uses this reference for a time base. At the end of each sampling window, the computer

Deep-Ocean Assessment and Reporting of Tsunamis (DART) BUOY, Fig. 3 Tsunameter block diagram showing how the components interact (Meinig et al. 2005)

reads the pressure and temperature data and stores the data in a flash memory card. A 15 s sampling period generates about 18 megabytes of data per year.

Computer The embedded computer system in both the buoy and the tsunameter was designed around the 32-bit, 3.3 volt Motorola 68332 micro-controller, and was programmed in C. It was built to be energy efficient for long-term battery powered deployment. The computer has 4 Mb of flash memory, a 12-bit A/D converter with 8 input channels, two RS232 channels, a hardware watchdog timer, a real-time clock, and 512 bytes of RAM. The embedded computer implements and regulates the primary functions of the surface and seafloor units: transmitting data communications, running the tsunami detection algorithm, storing and retrieving water column heights, generating checksums, and conducting automatic mode switching.

Acoustic Modem and Transducer A Benthos11 ATM-880 Telesonar acoustic modem with an AT-421LF directional transducer has a 40° conical beam which is used to transmit data between the tsunameter and the surface buoy. Modems transmit digital data via MFSK

modulated sound signals with options for redundancy and convolutional coding. Transducers are baffled to minimize ambient noise from entering the receiver.

Tilt Sensor Each tsunameter has a Geometrics 900-45 tilt sensor mounted in the base of one of the housings. This is used to determine the orientation of the acoustic transducer when the system has settled on the seafloor. If the tilt is greater than 10°, the tsunameter can be recovered and redeployed. The watch circle of the surface buoy could carry it out of the acoustic projection cone from the tsunameter if the angle from the vertical is too great.

Batteries The tsunameter computer and pressure measurement system uses an Alkaline D-Cell battery pack with a capacity of 1560 watt-hours. The acoustic modem in the tsunameter is powered by similar battery packs that can deliver over 2000 watt-hours of energy. These batteries are designed to last for 4 years on the seafloor; however, this is based on assumptions about the number of events that may occur and the volume of data request from the shore. Battery monitoring is required to maximize the life of the system.

Tsunami Detection Algorithm Each DART II tsunameter is designed to detect and report tsunamis autonomously. The Tsunami Detection Algorithm works by first estimating the amplitudes of the pressure fluctuations within the tsunami frequency band, and then testing these amplitudes against a threshold value. The amplitudes are computed by subtracting predicted pressures from the observations, in which the predictions closely match the tides and lower frequency fluctuations. If the amplitudes exceed the threshold, the tsunameter goes into Event Mode to provide detailed information about the tsunami.

Reporting Modes Tsunameters operate in one of two data reporting modes: a low power, scheduled transmission mode called “Standard Mode” and a triggered event mode simply called “Event Mode.”

Standard Mode reports once every 6 h. Information reported includes the average water column height, battery voltages, status indicator, and a time stamp. These continuous measurements

provide assurance that the system is working correctly.

Event Mode reports events such as earthquakes and/or tsunamis when a detection threshold is exceeded. The Tsunami Detection Algorithm triggers when measured and predicted values differ by more than the threshold value. Waveform data are transmitted immediately (less than a 3-min delay).

Tsunami waveform data continue to be transmitted every hour until the Tsunami Detection Algorithm is in a non-triggered status. At this point, the system returns to the Standard Mode.

Surface Buoy

The DART II surface buoy, shown in Fig. 4, relays information and commands from the tsunameter and the satellite network (Meinig et al. 2005). The buoy contains two identical electronic systems to provide redundancy in case one of the units fails. The Standard Mode transmissions are handled by both electronic systems on a preset schedule. The Event Mode transmissions, due to their

Deep-Ocean Assessment and Reporting of Tsunamis (DART) BUOY, Fig. 4 Block diagram of DART II surface buoy (Meinig et al. 2005)

importance and urgency, are immediately transmitted by both systems simultaneously.

The surface mooring uses a 2.5 m diameter fiberglass over foam disk buoy with a displacement of 4000 kg. The mooring line is 19 millimeter eight-strand plaited nylon line with a rated breaking strength of 7100 kg, and is deployed to maintain a tight watch circle, keeping the buoy positioned within the cone of the acoustic transmission. In temperate areas where fish tend to aggregate and bite lines, wire rope is used on the upper few hundred meters of the mooring.

Two downward-looking transducers are mounted on the buoy bridle at a depth of 1.5 m below the sea surface. A multilayered baffle system of steel, lead, and syntactic foam shields the transducers from noise and cushions them with rubber pads for a soft mount.

Modem and Acoustic Transducer The Benthos Telesonar acoustic modems and transducers are the same as used in the tsunameter. To improve the reliability of data transmission, two identical systems are used on the buoy.

Computer The computer is the same type used in the tsunameter as described in section “[Tsunameter](#)”. It processes messages from both the satellite and the tsunameter.

Iridium Transceiver A Motorola 9522 L-Band Iridium transceiver from NAL Research provides data connectivity via the Iridium Satellite Network. The buoy computer connects to the transceiver using an RS232 serial port. Data is transferred at 2400 baud similarly to the familiar dial-up modem connections. A typical Standard Mode report takes approximately 30 s, including the time it takes to complete the connection, transmit the data, and disconnect.

GPS A Leadtek model 9546 GPS receiver is used to maintain the buoy’s computer clock’s accuracy to within ~1 s of GMT. Additionally, a GPS position is reported once per day to monitor buoy position.

Batteries The buoy’s fiberglass well houses the system electronics and power supply, which is

made up of packs of D-cell alkaline batteries. The computer and Iridium transceiver are powered by 2560 watt-hour batteries; the acoustic modem is powered by 1800 watt-hour batteries. These batteries will power the buoy for at least 2 years.

The buoy is designed to mitigate the potentially dangerous build up of hydrogen gas that is naturally vented from alkaline cells. Design features include: (1) hydrogen getters (such as those from HydroCap Corp); (2) pressure relief valves; and (3) spark-free components such as fiberglass or plastic.

Data Communications

There are messages that are sent and received to and from the DART II systems. The data communications include workstation (on land) to buoy, tsunameter to buoy, buoy to satellite, and satellite to ground stations. Details can be found in Meinig et al. (2005) about how the data is physically transported over the distance between the hardware components, what information is contained in the messages and how the message is formatted.

Key Applications

As described above, the DART buoys observe and record changes in sea level out in the deep ocean so as to enhance the capability for early detection and real-time reporting of tsunamis before they reach land. During the application of DART systems, the following should be noted.

Site Characteristics

To reliably send and receive the acoustic packets to and from the tsunameter, which might be submerged between 1000 and 6000 m below the buoy, the tsunameter must be located on a relatively flat portion of the ocean floor, and the buoy must be moored such that it stays within a 40° cone; a cone whose vertex is at the tsunameter, and whose base encompasses the buoy. Outside of this cone, the signal-to-noise ratio deteriorates rapidly, and data integrity will be compromised (Meinig et al. 2005).

Deep-Ocean Assessment and Reporting of Tsunamis (DART) BUOY,

Fig. 5 The deployment of a DART™ buoy in the Tasman Sea (Bureau of Meteorology 2018)

The mooring needs to be strong enough to withstand harsh ocean conditions of wind, waves, currents, fish bites, and vandalism (Meinig et al. 2005).

Location for Deployment

The best location for deployment of a DART buoy is determined by careful consideration of a number of factors. The DART buoy needs to be far enough away from any potential earthquake epicenter to ensure there is no interference between the earthquake signal at the buoy and the sea-level signal from the tsunami. On the other hand, the DART buoy needs to be close enough to the epicenter to enable timely detection of any tsunami and maximize the lead time of tsunami forecasts for coastal areas. In addition, DART buoys must ideally be placed in water deeper than 3000 m to ensure the observed signal is not contaminated by other types of waves that have shallower effects (e.g., surface wind-waves). International maritime boundaries must also be considered when deploying DART buoy systems. Figure 5 shows the deployment of a DART buoy in the Tasman Sea by the Australian government (Bureau of Meteorology 2018).

In-Water Life

The life cycle of a deployed DART buoy system is approximately 2–4 years. The maintenance regime involves the replacement of the surface buoy and the sea-floor pressure sensor every 1–2 years. The

devices retrieved during regular maintenance are refurbished and made ready for the next redeployment (Bureau of Meteorology 2018).

Related Specifications

The design of mooring system is a complicated integrated system, including design specifications, sea conditions, characterization of floating structures, hydrodynamic performance, mooring line data, numerical simulations, data analysis and comparison, etc.

An industry widely recognized positioning system analysis specification and standard is an indispensable important reference in the entire design process. The specification mainly introduces the function, form, design, and analysis method of the floating structure positioning system and gives the corresponding design criteria. At present, there are four main types of analysis specification for mooring system commonly used worldwide:

1. API RP 2SK – Specification for design and analysis of floating structure positioning system
2. API RP 2SM – Specification for the design, manufacture, installation, and maintenance of positioning systems for mooring lines in the form of synthetic materials
3. DNV Offshore Standard-E301 – Marine engineering mooring positioning specification
4. ABS Guide for Building and Classing Floating Production Installations – Floating production and installation specifications

The above specifications specify the common design standards for mooring systems.

Considerations and Design Process

Considerations

In the initial stage of design, it is necessary to consider comprehensively various possible situations, so that reasonable and accurate analysis can be carried out in the later stage. The following factors mainly need to be considered (Huang 2000):

1. Design standards for mooring systems, design loads, design life, operational and maintenance requirements, etc.
2. The pipeline between the riser-type seabed and the production of the drilling platform, so its existence is one of the main limiting factors for the mooring system. It limits the displacement range of the platform and, importantly, the mooring line and the riser. The interaction between the waves and the current on the riser will increase the movement of the platform, which is equivalent to increasing the environmental load of the mooring system, but at the same time, the riser system has a certain rigidity. The mooring system has certain auxiliary functions.
3. The layout of the mooring system must take into account the layout of the subsea facilities, such as the distribution of the mid-sea system, the riser foundation, and the submarine pipelines. For the installation, operation, and

maintenance phases of the mooring system, the mooring lines cannot combine with the submarine facilities. There is any collision; otherwise there will be great damage to each other.

In addition to the above basic factors, the designer must also understand the potential failure risks of the mooring system and avoid dangerous situations during the design process. In API RP 2SK, the following conditions are usually considered: intact condition, damaged condition, and transient condition (Table 1).

Design Procedure

The first step of the mooring design process is basic data input, which mainly includes the basic characteristic parameters of the floating structure, its operation requirements, and working environment conditions. The basic characteristic parameters mainly include the main dimension of the structure, the profile diagram of the ship structure, the position of the center of gravity, the moment of inertia, the displacement under different design conditions, the draft, the layout of the upper deck structure, the wind receiving area, etc. If there is a turret system, it is also necessary to provide its exact position and size, structure type, and characteristic parameters, and there will be a big gap between the mooring method and the mooring material selection. Therefore, it is necessary to determine accurately the relevant parameters of the floating structure under different working conditions to ensure the rationality of the design of the mooring system. Multipoint mooring and single-point mooring are two common

Design of Mooring System, Table 1 Recommended analysis methods and conditions

Type of mooring	Analysis method	Conditions to be analyzed
Permanent mooring system		
Strength analysis	Dynamic	Intact/damaged
Fatigue analysis	Dynamic	Intact
Mobile mooring system		
Strength analysis	Quasi-static or dynamic	Intact/damaged/transient
Fatigue analysis	Not required	Not required

mooring methods. Multipoint mooring is a natural extension of the traditional form of ship mooring, that is, a certain number of mooring lines are symmetrically distributed around the platform, which can control the linear motion and the rotational motion of the platform. Multipoint mooring is simple and economical and can install more risers and umbilical systems. It is suitable for sea areas with better sea conditions or a single sea area with wind and waves. However, for a boat-shaped floating body, if it is subject to a large trajectory, the mooring line of the wave will be subject to a large load, and there is a risk of breaking. Common SPAR platforms, semisubmersible platforms, and some FPSOs use multipoint mooring. Considering the drawbacks of multipoint mooring of the boat-shaped floating body, a single-point mooring has appeared, allowing the hull to rotate freely around a single point, so that the bow always faces the maximum environmental load, thus effectively reducing the force of wind and waves (Liu 2012). Therefore, most FPSO mooring systems are single-point moorings. It is easy to operate, safe, flexible, and environmentally adaptable. However, compared to multipoint mooring, single-point mooring has higher manufacturing costs and more complicated technology. With the increasing demand, there are many types of single-point mooring, such as turret mooring, tower mooring, catenary buoy mooring (CALM), and single-anchor leg mooring system (SALM).

The type and function of the floating structure determine the choice of mooring materials and mooring methods. Therefore, the design of the mooring system first needs to determine the type, main purpose, and service life requirements of the floating structure. For permanent mooring systems, the working time is generally required to be several decades. For mobile mooring systems, the working time in the same sea area is shorter, which can be as short as several months, depending on the specific situation. In addition, restrictions on the use of risers or other pipelines or other structures and facilities around the floating structure, the displacement of the floating structure in certain directions is usually limited, and the mooring system has higher requirements.

Wind, wave, and current are the main environmental loads directly acting on the floating structure and its mooring system, and it decides whether the mooring system works safely (Fujii et al. 1982). Therefore, it is necessary to fully collect the long-term statistical data of the sea area and grasp the accuracy of each main characteristic parameter. It is no doubt that the working water depth is an important factor in determining how to choose the mooring form and the mooring line material. At the same time, the composition characteristics, slope, and seabed structure layout of the seabed soil also play a major role in the selection of the seabed anchor and the layout of the mooring system. Finally, we must also understand the climate change, atmospheric icing, tides, and growth of marine organisms in the sea area. The type and growth rate of seawater microorganisms will affect the quality of floating structures and mooring lines, hydrodynamic diameters, towing force coefficient, etc. In short, the more sufficient the understanding of the working environment conditions, the better it is to design a safer and more reasonable mooring system.

All the basic information is ready, that is, the design and scheme of the mooring system, including the choice of mooring method, the composition of the mooring line material and the length and material characteristics of each part, the floating structure fairlead, the determination of the anchor position, and the choice of the anchor type. The anchoring points fixed to the seabed are the critical part of a mooring system for keeping a floating structure on location. Depending on soil conditions and the required performance, there are various types of anchors that can be selected. The feasibility of the final design requires comparing the calculated results with the actual requirements. The API RP 2SK specification proposes the following four basic design guidelines. There are two types of anchor: conventional drag embedment anchors and anchors designed to resist vertical loads, such as pile, suction, and vertically loaded plate anchors. Finally, the floating structure and its mooring system are analyzed and calculated, and a reasonable calculation method is determined. The overall

motion response of the floating structure and the stress of the mooring line and the anchor are obtained. Comprehensively evaluate the rationality of the design of the mooring system. If there are any defects, make appropriate adjustments until the requirements are met.

Computational Methods

About the computational methods, the following aspects should be considered:

1. Frequency domain analysis, time domain analysis, and combined time and frequency domain analysis.

In the frequency domain analysis, the general equations of motion describing the response of the vessel are decoupled and analyzed separately for mean, low, and wave frequency responses. Statistical peak values, such as significant or maximum responses, are then evaluated based on certain peak response distributions. Finally, the wave frequency and low-frequency responses are properly combined to yield the maximum combined response for specific storm duration.

In the time domain analysis, the general equations of motion describing the combined mean, low, and wave frequency response of the vessel are solved in the time domain. The forcing functions include the mean, low frequency, and wave frequency forces due to wave, wind, current, and thrusters. The dynamic equations describing the vessel, mooring lines, risers, and thruster forces are all included in a single time domain simulation. Time histories of all system parameters (vessel displacements, mooring line tensions, anchor loads, etc.) are available from the simulation, and the resulting time histories are then processed statistically to yield expected extreme values. The time domain simulation should be long enough to establish stable statistical peak values.

In the combined time and frequency domain analysis, time and frequency domain solutions for mean loads, wave, and low-frequency motions can be combined in different ways. In a typical approach, the mean and low-

frequency responses (vessel displacements, mooring line tensions, anchor loads, etc.) are simulated in time domain, while the wave frequency responses are solved separately in frequency domain. The frequency domain solution for wave frequency responses is processed to yield either statistical peak values or time histories, which are then superimposed on the mean and low-frequency responses (API RP 2SK 2005).

2. Quasi-static and the dynamic analysis for the force analysis of mooring lines.

In the quasi-static analysis, the dynamic wave loads are taken into account by statically offsetting the vessel by wave-induced motions. Vertical motions and dynamic effects associated with mass, damping, and fluid acceleration on the mooring line are neglected. Research in mooring line dynamics has shown that the accuracy of tension predictions based on this method can vary widely depending on the vessel type, water depth, and line configuration.

In the dynamic analysis, the time-varying effects due to mass, damping, and fluid acceleration are accounted for. In this approach, the time-varying fairlead motions are calculated from the vessel's surge, sway, heave, pitch, roll, and yaw motions. Dynamic models are used to predict mooring line responses to the fairlead motions. Two methods, frequency domain and time domain analyses, can be used for predicting dynamic mooring loads. In the time domain method, all nonlinear effects including line stretch, line geometry, fluid loading, and sea bottom effects can be modeled. The frequency domain method, on the other hand, is always linear as the linear principle of superposition is used. Methods to approximate nonlinear effects in the frequency domain and their limitations should be investigated to ensure acceptable solutions for the intended operation (API RP 2SK 2005).

3. Non-coupling, semi-coupling, and full-coupling analysis for the processing of the coupling relationship between the mooring system and the floating structure.

In the non-coupling analysis, the structure and the mooring responses are analyzed separately. The following mooring/riser effects can be included: mooring system stiffness, direct current loads, and estimated slow drift damping. The structure static offset, the slow drift, and wave frequency motions are solved, and, based on the derived FPSO responses, mooring line responses are then predicted.

In the semi-coupling analysis, the mooring line dynamics are fully modeled. Using the wind, current, wave drift coefficients, and structure hydrodynamic coefficients, the structure responses are solved in the time domain taking into account the mooring line responses. It is assumed that the structure wave frequency motions are not affected by the mooring lines. Even though the mooring lines are not coupled with the structure wave frequency motions, their contributions to such motions are often negligible since the structure's inertia properties are an order of magnitude higher than those of the mooring lines.

In the full-coupling analysis, the mooring line dynamic responses are coupled to the whole range of structure responses, including the wave frequency responses. In this method, the complete system dynamic equations are solved simultaneously in the time domain (Luo and Baudic 2003).

At last, it should be pointed out that it is difficult to accurately calculate the low-frequency motion, especially the low-frequency motion damping. The evaluation of viscous damping has accumulated a certain amount of experience (Huse 1991). It is also considered in the low-frequency motion damping of computational analysis, but the mooring system damping is more complicated and difficult to accurately estimate, which is usually ignored. However, the study found that these damping are important, even larger than viscous damping. If ignored, it may lead to overestimation of low-frequency motion. For large ship structures, low-frequency motion is an important design factor and should be accurately evaluated for low-frequency damping. The accurate evaluation of low-

frequency motion damping remains to be further studied.

Feasibility Verification

The feasibility of the final design requires comparing the calculated results with the actual requirements. The APL RP 2SK specification proposes the following four basic design guidelines: limitation of motion displacement of floating structures, length of mooring line, ultimate bearing capacity of anchor, and mooring line breaking force. The extreme value of the mooring line tension is generally determined by its ratio to the minimum breaking strength (MBS) of the mooring line, i.e., the safety factor, and compares the calculated safety factor with the safety factor required by the specification. If the former is larger than the latter, the mooring line is safe, and the design of the mooring system is reasonable; otherwise, it is not safe, and the mooring system needs to be redesigned. The specification determines the safety factors of different analysis conditions and different analysis methods, which can be used as a basic standard for mooring system analysis (Table 2).

All in all, the design of the mooring system requires comprehensive consideration of the structural requirements, the environmental conditions, and the cost of its own construction. Theoretical analysis, numerical simulation, and model testing are the main design and verification methods. Although there are still some difficulties in some aspects, such as the limitation of the dimensions of the deepwater mooring model test in offshore basins, great progresses have been made.

Design of Mooring System, Table 2 Mooring safety factor

Condition	Analysis method	Tension limit (percent of MBS)	Factor of safety
Intact condition	Quasi-static	50	2.00
Intact condition	Dynamic	60	1.67
Damaged condition	Quasi-static	70	1.43
Damaged condition	Dynamic	80	1.25

Definition

Deepwater riser is the main connecting member between the floating offshore platform and the seabed wellhead, and it is the key part of the whole submarine pipeline system. Generally, there is high-pressure oil or air flow passing through the riser, and the external part bears the action of wave and current load (PRCI 1987). There are essentially two kinds of risers, namely,

rigid risers and flexible risers. A hybrid riser is the combination of these two. At present, there is no unified classification of deepwater riser, but according to its structure and use, it can be roughly classified as follows:

- Top tensioned risers
- Steel catenary risers
- Flexible risers
- Hybrid risers
- Drilling risers

Scientific Fundamentals

Top Tensioned Risers

Introduction

Top tensioned risers (TTRs) are used as the conduits between dynamic floating production units (FPU) and subsea systems on the sea floor, for dry tree production facilities such as spars and tension leg platforms (TLPs). Top tensioned riser (TTR) is one of the main configurations of riser systems, which has long been adopted to serve as the link between the floating production systems (FPSs) and the wellhead at the seabed for oil and gas transportation. For some TLP and spar applications, top tensioned risers provide a good solution. In this application, the flow line or pipeline terminates at a junction point beneath the structure (see Fig. 1). A straight riser is run down from the platform and terminates either in the same junction structure or in its own junction structure, in which case a short pipe section installed with the aid of an ROV connects the riser and flow line (API 1998).

In general, TLP risers use tensioners, whereas spar risers are tensioned by air cans, although one spar (Holstein) uses tensioners. Top tension ratios (ratio of top tension to riser apparent weight) vary greatly. On some TLPs, they have been designed to be as low as 1.2, while on others they have been in the range of 1.4–1.8. There is one significant difference between tensioners and air cans, resulting from the setdown of the riser top end as the platform is offset. In the case of tensioners, the top tension increases with platform offset because

Design of Pipelines and Risers, Fig. 1 Top tensioned riser

of tensioner stiffness. In the case of air cans, it is slightly reduced because of the compressibility of the air or gas in the cans.

General Design Considerations

The major design drivers of TTRs are, for instance:

- Allowable floater motions
- Allowable stroke of tensioning system
- Maximum riser top tension
- Size of stress joints and flex joints
- Keel joints
- Increasing length of riser joints
- Design criteria for the safety philosophy of liquid barriers, valve, and seals
- Current interface with array and vortex-induced vibration
- Impact between buoyancy cans and hull guides

Steel Catenary Risers

Introduction

Steel catenary risers (SCRs) are a preferred solution for deepwater wet tree production, water/gas injection, and oil/gas export (see Fig. 2). Statistics, illustrated in Fig. 3, demonstrates that the number of SCRs currently either under design or planned exceeds the current worldwide inventory of operating SCRs (Gelfgat et al. 2006).

Steel catenary risers are an elegant solution to the riser challenge of connecting to floating

production platforms in deepwater. These risers can be installed by laying a predetermined length of pipe, making the connections easier. They tolerate a certain amount of movement of the production platform, making them useful for TLPs, FPSs, FPSOs, and spars, as well as fixed platforms, compliant towers, and gravity structures. However, excessive motion can cause metal fatigue at or near the touchdown point and at or near the top support (Hatton and Willis 1998).

SCR Initial Design Analysis

In the pre-FEED phase, an initial design is carried out to define:

- Riser host layout (for interface with other disciplines)
- Riser hang-off system (flex joint, stress joint, pull-tube, etc.)
- Riser hang-off location, spacing, and azimuth angle (hull layout, subsea layout, total risers, and interference consideration)
- Riser hang-off angle for each riser
- Riser location elevation at hull (hull type, installation, and fatigue consideration)
- Global static configuration

A static configuration may be determined based on catenary theory accounting for hang-off angle, water depth, and riser unit weight). The SCR design shall meet basic functional requirements such as SCR internal (and/or

Design of Pipelines and Risers, Fig. 2 SCR (steel catenary riser) (William et al. 2011)

D

Design of Pipelines and Risers, Fig. 3 Number of SCRs installed/proposed worldwide (215 SCRs) (Bai et al. 2004)

external) diameters, submerged tension on host vessel, design pressure/temperature, and fluid contents.

Due considerations shall be given to future tie-back porches to accommodate the variations for hang-off system, riser diameter, and azimuth angles and the required extreme response and fatigue characteristics (Song and Stanton 2007).

Flexible Risers

Introduction

Petrobras pioneered the use of flexible pipe as risers starting in 1978. Because of the bending characteristics, flexibles are most appropriate for floating systems that experience significant vertical and/or horizontal movement. Flexible pipe, because of its beneficial bending characteristic,

is often used to make the connections from the production equipment on floating systems to the production and export risers (Neto and Mauricio 2001). Because of these same bending characteristics, these flexibles are also finding more

and more use as the primary risers. Today flexible pipes have been used as risers and flow lines in water depths down to 2,000 m (Fig. 4). Off-shore Brazil in the Campos Basin alone, approximately 4,000 km of flexible pipes have been deployed.

Model tests showed that flexible pipes could be used in the free-hanging mode but only in benign environments. In more severe environments, changes in lateral offset of the platform tended to induce unacceptably large variations in pipe tension and large changes in position of the touch-down point (TDP) at the seabed. To reduce those effects, a number of different architectures were developed for the section close to the seabed. Some of these are shown in Fig. 5.

Flexible Riser Design Analysis

The essential tasks for design and analysis of flexible risers are similar to those described for other types of risers; see below (Novitsky and Serta 2002).

- **Design Basis Document:** The document should as minimum include the following:
 - Host layout and subsea layout
 - Wind, wave, and current data and vessel motion that are applicable for riser analysis

Design of Pipelines and Risers, Fig. 4 Flexible pipe wall structure. (Courtesy of Technip)

Design of Pipelines and Risers, Fig. 5 Example architectures for flexible risers

- Applicable design codes and company specifications
- Applicable design criteria
- Porch and I-tube design data
- Load case matrices for static strength, fatigue, and interference analysis
- Applicable analysis methodology
- **FE Modeling and Static Analysis:** a finite element model is built, and a nonlinear static analysis is carried out assuming the vessel is in NEAR, FAR, and CROSS positions.
- **Global Dynamic Analysis:** A global regular wave dynamic analysis is carried out assuming the vessel is in NEAR, FAR, and CROSS positions. A sensitivity study is performed on critical parameters such as wave periods, effect of marine growth, and hydrodynamic coefficients.
- **Interference Analysis:** A dynamic regular wave analysis is carried out to check the minimum clearance between the risers and with the vessel system along the water column, for various predefined load cases. The interference analysis shall confirm the selection of riser hang-off angles and departure angles, etc.
- **Cross-Sectional Model:** a detailed cross-sectional model is built to calculate key cross-sectional properties such as bending stiffness, axial stiffness, FAT pressure, etc.
- **Extreme and Fatigue Analysis:** The wire and tube stresses are calculated at design pressure. An extreme response analysis is carried out using regular wave theory to estimate tensions, cyclic angles, etc. The cross-sectional model is then used to perform to fatigue analysis.
- **Design Review:** This includes check of global configuration, bell mouth design, interference and fatigue design, etc. In some special situations, upheaval buckling and onbottom stability of flexible flow lines are also checked, following pipeline design practice (Walker and Davies 1983).

Typically, a detailed design of flexible pipe is carried out by the supplier for the flexible pipe materials. A third party, normally a riser engineering company, is engaged to carry out a verification of the design, as aforementioned.

Hybrid Risers

Introduction

Fisher and Berner (1988) presented the systems details, engineering design, testing, and installation of the first hybrid risers. The hybrid riser (shown in Fig. 6) uses a rigid pipe for the vertical free-standing portion and a flexible pipe for the near-surface dynamic motion region. Top tension riser is used to hold a vertical riser when the well is underneath the floating structure. A pre-tension is applied to the riser, so the riser pipe will not be in compression when the floating structure moves down. Figure 7 shows hydropneumatic tensioner of which the piston cylinder in each tank works like a shock absorber of automobile.

Design of Pipelines and Risers, Fig. 6 Hybrid riser (Brian and Chris 2000)

Design of Pipelines and Risers, Fig. 7 Riser top tensioner

Preliminary Analysis

A single string approach may be taken to model the hybrid riser system:

- Mass, bending stiffness, and axial stiffness are the sum of all members.
- Buoyancy diameter is taken as the outside diameter of the buoyancy modules.
- Air can is a model using pipe elements with appropriate buoyancy and drag properties.
- Flexible jumpers are modeled individually or in group.

The key objective of the preliminary analysis is to get indication of the requirements for (Wald 2004):

- Buoyancy and tension distribution along the riser
- VIV suppression devices

Low submerged weight and low tension can make the riser susceptible to VIV. However, it is recommended to avoid over-specification of strakes, which can increase drag and may have negative effect on buoyancy requirements and stresses at riser base.

Drilling Risers

Introduction

Floating drilling risers are used on drilling semi-submersibles and drilling ships (see Fig. 8). As the water depth increases, integrity of drilling risers is a critical issue. The design and analysis of drilling risers are particularly important for dual operation, DP-based semi-submersible rigs. For the integrity assurance purpose, a series of dynamic analysis needs to be carried out. The objective of the dynamic analysis is to determine vessel excursion limits and limits for running/retrieval and deployment. In recent years, qualification tests are also required to demonstrate fitness for purpose for welded joints, riser coupling, and sealing systems. For risers installed in the Gulf of Mexico, vortex-induced vibrations are a critical issue. Some oil companies encourage use of monitoring systems to measure real-time vessel motions and riser fatigue damage. The monitoring results may also be used to verify the VIV analysis tools that are being applied in the design and analysis (Bai and Bai 2005).

Riser Design Criteria

Table 1 presents typical criteria to be used for determination of the operability limits for the drilling riser, defined mainly based on API 16Q.

For the drilling riser, the safety factor on fatigue life is 3 because the drilling joints can be inspected. The fatigue calculations are to account for all relevant load effects, including wave, VIV, and installation-induced fatigue. In some part (s) like the first joints nearest to the LFJ joint,

Design of Pipelines and Risers, Fig. 8 Drilling semi-submersibles, drilling ships, and drilling risers

Design of Pipelines and Risers, Table 1 Criteria for drilling riser operability limits

Design parameter	Definition	Drilling conditions	Non-drilling conditions
Low flex joint angle	Mean	1°	NA
	Max	4°	90% of capacity (9°)
Upper flex joint angle	Mean	2°	NA
	Max	4°	90% of capacity (9°)
Von Mises stress	Max	67% of σ_y	80% of σ_y
Casing bending moment	Max	80% of σ_y	80% of σ_y

the fatigue life could be less, in which case the fatigue life will determine the inspection interval.

Drilling Riser Analysis Methodology

Some keywords for drilling riser design and analysis are shown in Fig. 9 from structural analysis

point of view; a drilling riser is a vertical cable, under the action of currents. The upper boundary condition for the drilling riser cable is rig motions that are influenced by rig design, wave, and wind loads. One of the key technical challenges for deepwater drilling riser design is fatigue of VIV due to (surface) loop currents and bottom currents (Bai and Bai 2005).

ALS – Accidental limit states; DLC – Design load cases; FLS – Fatigue limit states; LS – Limit states; PSF – Partial safety factors; SLS – Serviceability limit states; ULS – Ultimate limit states

Definition

Design is the creation and specification of a structure that fulfills the requirements of functionality, serviceability, and survivability during its lifetime.

Introduction

Renewable energy devices exist in various forms. Wind turbines, wave energy converters, tidal turbines, and photovoltaic systems are typical devices that convert energy, respectively, from wind, wave, tidal, and solar resources into electrical power.

Figure 1 (left) shows an offshore wind turbine which is composed of blades, nacelle, drivetrain, control systems, support structures, and so forth. During operation, the cyclic revolutions of the rotor are driven by the aerodynamic, gravitational, and inertial loads on the blades. The kinetic energy is further transferred to the electrical generator through the drivetrain. In a wind turbine, most components are designed separately by industrial partners with the aim to achieve similar level of probability of failure. Such a wind turbine system may be subject to complex external loading conditions including gust wind (Bierbooms

et al. 1999), wave impacts (Chella et al. 2012), biofouling (Degraer et al. 2010), and seabed scour (Prendergast et al. 2015) during the design life. Internal conditions may arise including mechanical system failures and faults. As operational and maintenance experiences are gained from the industry, the designs of commercial offshore wind turbines are increasingly improved. For instance, generally, upscaled wind turbines with greater rotor diameters are considered more cost-effective designs, and the direct-drive technologies are often applied to avoid gearbox failures.

A concept of wave energy converter is also schematized in Fig. 1 (right). This concept was invented in the 1970s and was officially named “the Edinburgh duck” (Salter 1974). As illustrated, the rotor has a pear shape. The power takeoff rocks and turns over as waves pass by, transferring the energy of the impact to pumps. Such a device usually consists of components like rotor, hydraulic components, and generator.

Compared to wind turbines, wave energy converters are less mature commercially. Although a multitude of concepts have been proposed and tested through modeling and wave-tank tests, only a few designs progressed to sea testing. Design of such renewable energy devices is not standardized and faces challenges case by case. To account for the uncertainties in real-life scenarios, novel designs are usually conservative concerning the consumption of materials, and prototypes are needed to demonstrate the feasibility.

In the following, the focus will be on the design philosophy of structural components of offshore wind turbines which can be representative of other renewable energy devices that are industrialized.

Limit States (LS)

Any structural components in a renewable energy device can fail if the actual load effects exceed

Monopile-type offshore wind turbine

the Edinburgh duck wave energy converter

Design of Renewable Energy Devices, Fig. 1 Schematics of an offshore wind turbine and a wave energy converter

certain limits. Here, R is defined as a resistance and S is defined as a load effect. To ensure that the structural performance is in a desirable state, Eq. (1) must be satisfied with a high probability of occurrence. If such a relation is not satisfied, the structural performance is undesirable. The boundary between the desirable and undesirable domains is called a limit state; refer to Eq. (2).

$$R \geq S \quad (1)$$

$$R = S \quad (2)$$

Such relations are general and can be formulated for various failure modes. The ultimate limit states (ULS) correspond to the ultimate resistance for carrying loads. Some examples of ULS are (DNV GL 2014):

- Excessive yielding and buckling
- Loss of static equilibrium of the structure, e.g., capsizing
- Transformation of the structure into a mechanism

Among these examples, the loss of static equilibrium applies particularly to floating structures.

Fatigue refers to the cumulative damage due to fluctuating stresses and strains. Fatigue limit states (FLS) can be formulated based on the fracture mechanics or the S-N curve-based approaches; see Lassen and Recho (2013). Most of the design rules use the S-N curve-based approach.

Accidental limit states (ALS) are related to accidental loads which have relatively low occurrence rate but may have severe consequences. For

bottom-fixed offshore wind turbines, ship collision can be a typical scenario (Bela et al. 2017; Moulas et al. 2017). For floating renewable energy facilities with mooring systems, loss of mooring lines can also be a consideration.

Serviceability limit states (SLS) can be formulated based on specific requirements of engineering projects. For instance, large deformation of wind turbine blade tips may be treated as an SLS condition because of possible interference with the tower structure during operation. Because the settlements of foundations can cause tilting of the turbine structures which is not permitted, other SLS should be established accordingly.

Categorization of the abovementioned LS is like that of offshore steel structures (DNV GL 2014).

Design Methods

Design of the structural components is an iterative process, and one needs to choose the design parameters and understand the loads and load effects. Two design approaches for load-bearing modern structures are presented in Fig. 2. In the deterministic approach, Eq. (3) gives an simplified expression for the design load (S_d). In Eq. (3), ψ is the safety factor, and S_k is the characteristic value of the load effect. ψ is chosen such that the possibility of unfavorable deviations of the characteristic values can be accounted for. Safety factors can be empirical and are not fully representative of the uncertainties the structure components are exposed to during the service life. Consequently, choice of

Design of Renewable Energy Devices,

Fig. 2 Design approaches for modern structures. (Adapted from Choi et al. 2006)

design parameters based on this approach often leads to over- or under-designed systems.

$$S_d = \psi \cdot S_k \quad (3)$$

As an improvement over the deterministic approach, the probabilistic (stochastic) approach addresses the uncertainties relating to loads, materials, and analysis methods and formulates the LS functions for critical failure modes explicitly. Then, the failure probability of structural members can be estimated using the structural reliability methods including Monte Carlo simulation, first-order reliability method, or second-order reliability method (Ditlevsen and Madsen 1996). In practice, the failure probabilities are often small, and the calculations of crude Monte Carlo simulations are inefficient. Improved reliability methods like the subset simulation technique (Au and Beck 2001) have been developed in recent years. The probabilistic method is applicable to design and analysis of modern civil engineering structures including offshore wind turbines (Jiang et al. 2017). Using this method, the aim is to design all components with a consistent level of reliability or safety and to achieve minimal cost with optimal design parameters (Sørensen and Toft 2010). Although such an approach typically yields robust and economical designs, the full probabilistic approach can be complicated to designers, as the design standards provide no procedures for performing structural reliability analysis. Particularly, for the design of new structures, various uncertainties related to physical model, numerical model, loads, and resistances need be assessed. Thus, the probabilistic approach is more often used in research projects and calibration of partial safety factors (PSF).

The method suggested by international standards (IEC 2007, 2009; GL 2010, 2012; DNV 2014) is a semi-probabilistic approach which is a medium between the deterministic and probabilistic approaches. This is also the most common approach for performing code checks of offshore wind turbines. Using the semi-probabilistic approach, PSF for loads or materials are applied in the design checks of the LS. These PSFs are calibrated by a code committee based either on

statistical evaluation of experimental data, field observation (CEN 2002), or preferably, structural reliability methods (Ditlevsen and Madsen 1996). For loads and materials, Eqs. (4) and (5) can be used to calculate the characteristic values (IEC 2007).

$$S_d = \gamma_f \cdot S_k \quad (4)$$

$$R_d = \frac{1}{\gamma_m} \cdot R_k \quad (5)$$

where S_k is the characteristic value of the load effect, S_d is the design value of the load effect from given design load cases (DLC), R_k is the characteristic value of resistance, R_d is the design value of resistance, and γ_f and γ_m are the load and material factors, respectively. In practice, a set of PSF are applied to account for the uncertainties in different load effects and materials. Refer to Ronold et al. (1999), Ronold and Larsen (2000), Tarp-Johansen et al. (2002), Márquez-Domínguez and Sørensen (2012), and Sørensen and Toft (2014) for calibration of PSF of wind turbine components. In a wind turbine system, some parts are nonredundant and more critical than others. Based on the consequence of failure and component classes, additional PSF should be multiplied with the load effect. Note that the PSF should be applied in conjunction with the DLC. The design standards divide the type of design situations into three main categories. For normal scenarios such as power production and transport scenarios, relatively high PSF are specified. For abnormal scenarios including control or protection system faults, low partial factors are recommended. Three representative PSF from IEC 61400-3 are listed in Table 1. The classification society DNV GL recommends PSF for design of support structures and foundations for wind turbines according to a target annual probability of failure of 10^{-4} (DNV 2007).

Design of Renewable Energy Devices, Table 1 Partial safety factors for unfavorable loads (IEC 2009)

Type of design situation		
Normal	Abnormal	Transport and erection
1.35	1.1	1.5

Analytical and numerical design methods are useful. Model testing and full-scale tests, albeit at high expenses, can be important supplements to validate numerical codes and check unknown effects (Nielsen et al. 2006; Myhr et al. 2011).

Design Load Cases

A set of DLC are specified by the design standards covering the most significant load conditions that a renewable energy device may experience during its lifetime. Table 2 summarizes the eight design situations recommended by the international

Design of Renewable Energy Devices, Table 2 Design load cases from IEC 61400-3 (IEC 2009)

Design situation	Type of analysis
1 Power production	Ultimate, fatigue
2 Power production plus occurrence of fault	Ultimate, fatigue
3 Startup	Ultimate, fatigue
4 Normal shutdown	Ultimate, fatigue
5 Emergency shutdown	Ultimate
6 Parked (standing still or idling)	Ultimate, fatigue
7 Parked and fault conditions	Ultimate, fatigue
8 Transport, assembly, maintenance, and repair	Ultimate, fatigue

electronical commission for offshore bottom-fixed wind turbines. Each situation is composed of a few cases of wave and wind conditions recommended for analysis. As shown, ultimate and fatigue analysis are required for most design situations including transport and maintenance. Note that some DLC are more clearly specified than others. The DLC related to faults (DLC 2 and DLC 7) are unclear as to what kind of faults should be considered and which structural components are concerned. Such cases, if ignored, may lead to nonconservative design of wind turbines. According to Jiang et al. (2013a), Jiang et al. (2015), and Etemaddar et al. (2016), DLC 2 can be a critical design situation. The transient responses due to pitch mechanism fault and shut-down can impose significant loadings on the main shaft. A time series of the main-shaft loading from numerical simulation is presented in Fig. 3. In comparison with the cases with power production plus fault (DLC 2), the parked conditions with pitch mechanism faults do not necessarily give greater structural responses than the parked cases (DLC 6) (Jiang et al. 2013b). The transport and assembly cases of wind turbine need be considered at the design stage, too. Still, there is limited research work on this aspect (Wang et al. 2014; Jiang et al. 2018). IEC 61400-3 specifies additional DLC covering ice loads if the wind turbine

Design of Renewable Energy Devices, Fig. 3 Time series of the main-shaft equivalent bending moment (Adapted from Jiang et al. 2013c)

shall be installed at an offshore site affected by sea ice. As shown by Shi et al. (2016), ice loads can induce significant tower vibrations of monopile-type wind turbines.

There are special design considerations for floating renewable energy devices: intact and damaged stability, station-keeping capability, analysis duration of short-term simulations, and installation challenges, to name a few. Although relevant design standards have been proposed (ABS 2013; DNV 2013), the DLC for floating wind turbines have not been addressed explicitly.

Design Procedure

Figure 4 presents the design procedure of the semi-probabilistic method recommended by

Design of Renewable Energy Devices, Fig. 4 Flow-chart for semi-probabilistic design procedure. (Adapted from IEC 2009)

international standards. First, the design parameters are chosen possibly based on baseline models. Then, the recommended DLC will be used in the assessment of design load effects. Numerical modeling is often involved. Integrated dynamic analysis considering the simultaneous actions of wind loads, wave loads, and control actions (if any) is carried out for support structures including the wind turbine tower to determine the design load effect if the dynamic response is of primary concern. Finally, the design load will be compared against the structural resistance in the code check. If the general condition of Eq. (1) is not satisfied, more iterations are involved to modify the design parameters. The design problem can often be formulated mathematically as an optimization problem, and different numerical tools can be integrated to automatize the workflow. Design optimizations of renewable energy devices can be found in Hu et al. (2012, 2016), Kurniawan and Moan (2013), and Yang et al. (2015).

Definition

Design of a submersible is the creation of a plan for the construction of a submersible. Designing often necessitates considering the aesthetic, functional, economic, and sociopolitical dimensions of both the design object and design process. It may involve considerable research, thought, modeling, interactive adjustment, and redesign. More specifically, design is a specification of a certain type of submersibles which is manifested by a user and intended to accomplish certain missions in a particular environment using a set of primitive components, satisfying a set of requirements, subject to certain constraints.

Scientific Fundamentals

Basic Definitions About the Design Process

A mission system is any object or process, or group of objects or processes, created to serve some useful purpose or mission, the mission being defined by a set of mission requirements (Allmendinger 1990). It is often convenient to picture a system as isolated from its surroundings by a boundary for the purpose of studying its internal behavior and interaction with its surroundings. Figure 1 provides such a diagram, in this instance showing a mission system designed to serve one or more underwater missions. Note that the mission system boundary encloses M individual or (I) systems, each enclosed by its own boundary, illustrating the aforementioned fact that the mission is accomplished by a submersible supported by other systems. The mission system diagram in Fig. 1 provides an example of these (I) systems in which it is assumed that mission requirements dictate the needs, among others, for the submersible's transportation by air and on the surface of the sea as well as for its launching, recovery, and support while submerged. As shown, (I_1) is the submersible, (I_2) is a transport aircraft, (I_3) is a surface support ship, and the last individual system, whatever it may be, is designated (I_M) (Allmendinger 1990).

Mission system design or the design of any of its individual systems including the submersible generally includes the three processes: *pre-design*, *design*, and *post-design* processes. The predesign process involves the potential user/owner of the system to be designed and is concerned with the development of the primary input to the design process – the *mission statement* and *mission requirements*. The design process conceives the mission system that is feasible and meets the mission requirements in as optimal a manner as possible. It is divided into *basic*, *contract*, and *detail design* phases – basic design being subdivided into *conceptual* and *preliminary design* stages. Finally, the post-design process is composed of three activities which are discussed briefly – construction and *alteration* of “new” and “existing” individual systems of the mission system, test and *evaluation*, and *operation*.

Design of Submersibles, Fig. 1 The mission system and its subsystems (Allmendinger 1990)

Experiences gained from these activities form, collectively, important “feedback” input to the design of future systems.

The design of many mission systems begins with most of the potential (I) systems already existing and some nonexistent. Existing systems require from no to extensive alterations to convert them to (I) systems, within a particular mission system, with commensurate amounts of design effort, construction, and costs involved. Obviously, the extent of alterations required is a primary consideration in choosing between candidate (I) systems. Nonexisting (I) systems,

of course, must be designed and constructed “from scratch” and are often the most costly of these systems.

The design of any (I), (S), or smaller system also begins with at least some of its individual systems existing. These existing systems, requiring no or small modifications, are often referred to as “off-the-shelf” items. Their use significantly reduces costs.

Design of any mission system, and not necessarily any of its individual (I) systems, should achieve the design goal of *satisfying a given set of mission requirements in as optimal a manner*

as possible considering the design constraints acting. This statement introduces two new topics of *design optimization* and *design constraints*. Optimizing a mission system's design is usually based on maximizing its *cost-effectiveness* (CE) to the extent possible given the constraints acting. This process may vary from relatively simple to complex depending on the nature of the mission system. In general, it requires extensive economics and experiential data and the use of sophisticated techniques.

The design of the mission system should lead to the selection of its (I) systems and their characteristics which tend to reduce the number of unproductive days. In this regard, important considerations include (1) basic design philosophy, (2) speed of transit to, from, and between stations or operating areas, (3) endurance of the support system, (4) maintenance and repair facilities, and (5) limiting weather/sea-surface conditions for operation and survival.

Consideration (1) focuses on the virtues of keeping (I) system components as simple and rugged as possible, thereby promoting system safety and reliability. As will be seen, this philosophy encourages the use of the design criterion that designs, particularly of critical systems, be based on state-of-the-art technologies – that is, on proven technologies. The contributions of this philosophy to increasing 5 days per year, as well as to operational safety, are obvious.

Consideration (2) focuses on the speed requirement for the (I) system providing transportation usually a surface ship. This speed should be as high as feasible, and the ship's seakeeping characteristics should permit its maintenance under reasonably adverse sea conditions. This consideration may also lead to the choice of more than one system for transportation, particularly if mission requirements emphasize high in-transit speeds or short response times. The use of an aircraft to fly a submersible and associated gear to a distant port to be placed on board a surface ship is a case in point.

Consideration (3) involves the ability of the support system to remain at sea for a specified length of time, which is usually given as a mission or performance requirement. It is concerned with characteristics such as fuel, freshwater, and provisions and stores capacities and habitability. Habitability has to do with all aspects of design relating to human comfort and is directly related to endurance of personnel and the level of work performance. It increases in importance as endurance increases.

Consideration (4) includes facilities that are vital to the success of the mission as well as to reducing the unproductive, on-station time facilities that maintain the submersible in a state of operational readiness. They may be an integral part of the support system or another (I) system closely associated with the submersible. In the latter instance, these facilities are housed in portable vans which are outfitted at the shore facilities and secured to the deck of the support ship for the cruise. In both instances, the facilities include personnel trained in specific areas of technology such as mechanical and electronic technicians. These persons, including the pilot, are referred to as the "submersible's crew" to differentiate them from the "ship's crew" and other groups of personnel on board.

Consideration (5) involves two environmental factors: weather conditions, with visibility and wind forces being principal concerns, and sea-surface conditions as measured by sea-state numbers from 0 to 9, severity of conditions increasing as these numbers increase. One or both factors, if adverse, can cause a serious increase in unproductive in-transit and on-station time as well as endangering survival of any transport-support system subjected to these elements. Consequently, the design or choice, or both, of (I) systems should consider ways and means of reducing this unproductive time to the extent possible. The three (I) systems primarily involved are the *transport-support*, *submersible*, and *launch-recovery* system.

There are numerous design constraints imposed on the mission system and its individual systems. They may be placed into one of three categories: *mission external design* constraints (MEDCs), *mission internal design* constraints (MIDCs), and *design criteria* (DC).

Mission external design constraints (MEDCs) are the constraints lying outside, or external to, the mission system boundary, indicating that they are independent of all mission considerations: that is, they exist irrespective of the mission system in question. MEDCs imposed on system design may come from a few or several of the following sources: (1) environmental, (2) technological, (3) economical, (4) legal/quasi-legal, (5) political, (6) sociological, (7) physiological, and (8) psychological. The designer's control over MEDCs varies from none to considerable.

Mission internal design constraints (MIDCs) are the constraints lying inside, or internal to, the mission system's boundary or inside the boundary of any (I) or lower-level system. These sources are the interactions between the systems that influence each other's designs.

Design criteria (DC) are the criteria which furnish standards for judgments regarding design procedures and for selecting system components. The use of specified structural formulations and the requirement that critical system components be based on state-of-the-art technology are examples. The basis for optimization, either cost-effectiveness or minimum weight, may also be considered as a design criterion. These criteria may be generated by the user/owner, the designer, or classification certification bodies.

Basic Introduction to the Design Process

The design and associated processes are diagrammed in Fig. 2 in chronological order as the (1) predesign, (2) design, and (3) post-design processes. In this section, they are introduced briefly from the perspective of the mission system to provide an overview of the entire subject.

The predesign process leads to the formulation of the basic input to the design process the mission (s) statement(s) and associated mission *requirements*. It is undertaken by the potential user or owner of the mission system to be designed, independently or in consultation with the system's designer.

The mission is a short, concise statement of what the user/owner wants the submersible to accomplish underwater. Missions may be categorized in several ways. The most general way is by the titles of the user community being served: (1) industrial/commercial, (2) military, (3) scientific, or (4) recreational. A subcategorization may be based on terms describing the general nature of the underwater tasks to be performed, for example, (1) *inspection*, (2) *survey*, (3) *monitoring/sampling*, (4) *construction*, (5) *maintenance/repair*, (6) *search*, (7) *salvage*, (8) *rescue*, and so forth. Mission system design may be based on single or multi-mission requirements, the latter including two or more categories of underwater tasks.

The design process is composed of three design phases: (1) *basic design*, (2) *contract design*, and (3) *detail design*. The levels of labor, preparation time, and costs associated with each phase increase exponentially as the process progresses. Design creativity and flexibility are essentially limited to the basic design phase – the mission system, including its submersible system, being well defined at the beginning of contract design.

Basic design is the primary design phase concerned with *how best* to accomplish *what* the potential user/owner of the mission system wants to do underwater as set forth by his mission requirements. In general, this phase involves:

1. Development of performance requirements, or (I) system capabilities, from the mission requirements
2. Determination of the principal characteristics of the (I) systems required to achieve these capabilities, which enable new construction systems to be designed and existing systems to be selected and altered if necessary

Design of Submersibles, Fig. 2 Design and associated processes (Allmendinger 1990)

3. Estimation of capital and operating costs of (I) systems
4. Identification of one or a few mission systems from among a series of alternatives which optimally meet performance requirements to the extent possible considering design constraints acting.
5. Refining and firming up characteristics and cost estimates of the (I) systems composing the optimum conceptual design(s)

The *conceptual design stage* of basic design is concerned with the first four of these functions – function four, herein, is based on cost-effectiveness as the optimization criterion. The *preliminary design stage* of this phase is concerned with the fifth function.

Conceptual design, diagrammed in Fig. 3, is the first attempt to translate all the user/owner's mission requirements into performance requirements and characteristics of the (I) systems composing the mission system. It is often viewed as consisting of *feasibility studies* and *completion* of the *optimum conceptual design(s)* once they are identified by these studies. Feasibility studies are concerned with the development of those performance requirements and associated system characteristics which have significant impact on the cost-effectiveness optimization process. Completion of the optimum design(s) involves developing other major performance requirements and characteristics those which are essential in defining (I) systems but which do not have significant impact on the optimization process.

Feasibility studies create an orderly series of mission system alternatives, all of which meet the mission requirements and are technically feasible, and select one or a few of these alternatives as the conceptual design(s) to be carried on into preliminary design. These alternatives are shown in Fig. 3 as $MS_1, MS_2, \dots MS_i$, where "i" can be any small to large number depending on the simplicity/complexity of the mission and optimization techniques used. As indicated in the figure, each alternative is composed of a unique combination of (I) systems. Each (I) system, in turn, has unique capabilities, characteristics required to achieve these capabilities, and costs associated with providing these characteristics. Certain unique (I) systems may appear in more than one combination, but individual combinations are not duplicated in other alternatives. Mission system alternatives may be generated by (1) varying performance requirements with the cascading effect of varying (I) systems' capabilities, characteristics, and costs and (2) varying (I) systems' capabilities, characteristics, and costs in ways each of which meet a specific set of performance requirements. Alternatives generated in this manner contain information necessary to conduct the

search for the optimum, cost-effective mission system(s).

Combinations of (I) systems forming mission system alternatives may vary in *number*, *type/capabilities*, and *status*. These features are related to functions required to accomplish mission tasks, the time frame for completing these tasks, if critical, and economic considerations. A *mission profile*, derived from mission requirements, is useful in providing functions and time frame information – its usefulness increasing as the complexity of the mission increases. This profile is a chronological listing of all events occurring from the mission's beginning to end and including time frame data where necessary.

Preliminary design is the second stage of basic design and is concerned with this phase's fifth function. Starting with baseline data provided by the selected conceptual design(s), it refines and firms up the major characteristics of (I) systems, the MIDCs they exert on each other, and cost estimates associated with them. In summary, it provides a precise engineering definition of the mission system and assurance that the design goal can be attained.

Contract design requires yet further refinement of design and additional detail. It yields contract plans and specifications necessary for interested parties to bid on the construction of new (I) systems or the alteration of existing (I) systems. It also provides contractual documents for the construction and alteration work.

Specifications delineate quality standards of material and workmanship as well as setting forth performance expectations for the (I) systems and their subsystems. They also describe tests and trials which must be performed successfully before acceptance of the systems.

Detail design is the final phase of the design process and entails the development of detailed working plans from which the (I) systems are constructed or altered. In one sense, it is really not a design phase since all the creative design effort is done in the preceding phases, the design being unequivocally defined prior to entering this phase. It does, however, require the greatest amount of work of all the phases and is often undertaken by entities building or altering the system.

Design of Submersibles, Fig. 3 Conceptual design of mission system (Allmendinger 1990)

The post-design process is composed of three activities: construction/alteration, test and evaluation, and operation. Although this publication is not directly concerned with these activities, there are two reasons for including them in this overall perspective: (1) They constitute important sources of input to new designs and feedback to the design in question, and (2) they are subject to certain existing MEDCs and will influence the future impact of MEDCs on following designs.

The above introduction mostly came from Allmendinger (1990) which was based heavily on Busby (1976). More detailed introduction can be found from Busby (1990) and Funnel (1999).

Historical Development of Submersible Design

Design of shallow water submersible may be started at very early days. While it is difficult to pinpoint the advent of the first submersible,

Askew (2001) attributed this to Cornelius van Drebbel who constructed a vehicle in 1620 under contract to King James I of England. It was operated by 12 rowers with leather sleeves, waterproofing the oar ports. It is said that the craft navigated the Thames River for several hours at a depth of 4 m and carried a secret substance that purified the air, perhaps soda lime? However, Kohnen (2009) attributed the first “submarine” to the American Turtle, built in 1772 by David Bushnell during the American Revolution. This particular submersible did not have any practical achievement; however, it is the first to have all systems needed for making a submarine, ballast and trim control, tubes for ventilation, and vertical and horizontal propulsion, and demonstrates classic ingenuity paired with military motivation. However, design of the deep manned submersible came from the idea of William Beebe and Otis Barton’s bathysphere which is actually not a submersible (Hotta et al. 2001). Barton and Beebe set a world record on August 15, 1934 near Bermuda by descending with their bathysphere to a depth of 923 m (Beebe 1935). Basically, it was just a steel sphere with one entry hatch and three large (8.0 in.) windows. These are made of fused quartz, 3 in. thick which were the largest pieces ever made at the time. The use of a cable to lower down the sphere provided many limitations such as depth and maneuverability. Kohnen (2009) pointed out that the following features of the bathysphere were unattractive:

1. The bathysphere was lowered by a tether which could cause discomfort by surface motion of the mothership (Piccard 1956).
2. The possibility of cable breakage caused by load-induced strain (Piccard 1956).
3. The quartz material for the windows was brittle and could fracture (Piccard and Dietz 1961).

The bathysphere cannot be described as a deep manned submersible since it does not have a moving ability, and due to self-weight of the cable, the maximum depth of deployment was only around 3000 m. In order to penetrate deeper in the ocean, people needed to seek a solution without a cable.

This problem was overcome by August Piccard who applied a balloon principle to the design of deep manned submersible. The Swiss-designed but mostly Italian-funded Trieste was an important bridge between the early US submersibles and the American-built deep submersibles that followed its purchase and operation by the US Navy. The catalytic effect of the Navy Trieste program was a major factor in the initiation of deep submergence technology in the United States. On January 23, 1960, the bathyscaph *Trieste*, piloted by Jacques Piccard and Don Walsh, made one successful dive to the depth of 10,913 m of the Challenger Deep. The details of this exploration can be found in many articles (e.g., Walsh 2009; Forman 2009; Kohnen 2009) and even books (e.g., Piccard and Dietz 1961; Busby 1976; Ballard and Hively 2002).

The technical achievements made in both *Trieste* and *Archimede* were great. These included (Kohnen 2009) (1) the underwater balloon principle that is still used even today, (2) the window design of acrylic that has become more or less the standard, and (3) a full ocean depth manned cabin for three persons. However, their drawbacks were also obvious (Kohnen 2009): (1) it was heavy and bulky; (2) it had poor maneuverability; (3) there was danger of fire when pumping gasoline in and out; and (4) swimmers did not enjoy when gasoline leaked into the water.

Due to the occurrence of solid buoyancy material (Allen 1955), the manned submersible became much smaller. Alvin was the most famous (Kaharl 1990; WHOI 2018), while other large depth manned operational submersibles include Nautille of France (Lévêque and Drogou 2006), MIR I and II of Russia (Sagalevitch 2009), Shinkai 6500 of Japan (Takagawa 1995), and Jiaolong of China (Cui 2013).

Since the 1960s, various other types of underwater submersibles were developed such as remotely operated vehicles (ROVs) (Christ and Wernli 2014), autonomous underwater vehicles (AUVs) (Wynn et al. 2014), hybrid ROV and AUV (HROV or ARV) (Bowen et al. 2004), gliders (Rudnick 2015), floats (Richardson and John 2001), etc., and their design philosophy can be found from the references provided.

Similarly, design method is also progressing. Earlier design was mostly experience-based and carried out with a design spiral in series. This is called empirical design. Nowadays, design is carried out more toward the first principle based, and very frequently the uncertainties embedded in the design process are explicitly considered. This is termed reliability-based design. In parallel, the optimization method is progressing, and the optimal design is achieved more globally than previous optimization

methods by introducing the idea of multi-disciplinary design optimization (MDO). For interested readers, one can refer to Pan and Cui (2018).

Key Applications

Submersibles have many uses worldwide, such as oceanography, underwater archaeology, ocean exploration, adventure, equipment testing, maintenance and recovery, and underwater videography. The application of submersibles has been introduced in submersible entry, and here we only emphasized two most important uses.

New Scientific Discovery

Between 1973 and 1974, project FAMOUS (French-American Mid-Ocean Undersea Study) was conducted in the Mid-Atlantic Ridge off the Azores using the French bathyscaph *Archimede* and the US submersible *Alvin*. The project was the first systematic and successful use of deep submersibles for science. They discovered and sampled fresh pillow lavas and lava flows at 3000 m deep in the rift valley, where the oceanic crusts were being created, providing

Design of Submersibles, Fig. 4 Extraordinary, unexpected life forms discovered by *Alvin* in the Galápagos Rift in 1977 (www.whoi.edu)

Design of Submersibles, Fig. 5 The B28RI nuclear bomb, recovered from 2,850 ft (870 m) of water, on the deck of the USS *Petrel*. (Picture from https://en.wikipedia.org/wiki/1966_Palomares_B-52_crash)

visual evidence of plate tectonics (WHOI 2018). In 1977, *Alvin* discovered a hydrothermal vent and vent animals in the East Pacific Rise off the Galápagos Islands at a depth of 2450 m. Discovery of these chemosynthetic animals, which were not dependent on photosynthesis, had a profound impact on biology in the twentieth century (Fig. 4) (Corliss et al. 1979).

Salvage of H-Bomb

In 1966, the US Navy called in *Alvin* to help find a hydrogen bomb accidentally dropped into the Mediterranean Sea. *Alvin* locates the bomb, and after the bomb skids down a slope on the first recovery attempt, it finds it again at a depth of 2,900 ft (880 m). Then, an unmanned torpedo recovery vehicle, CURV-I, became entangled in the weapon's parachute while attempting to attach a line to it. A decision was made to raise CURV and the weapon together to a depth of 100 ft (30 m), where divers attached cables to them. The bomb was brought to the surface by USS *Petrel* (Fig. 5).

- Serve as a contractual reference document between suppliers and purchasers
- Serve as a guideline for designers, suppliers, purchasers and regulators

And it usually gives requirements for the following:

- Design principles
- Structural categorization
- Material selection and inspection principles
- Design loads
- Load effect analyses
- Design of steel structures and connections
- Corrosion protection
- Foundation design

For marine structures, a design rule or standard is mainly developed by classification societies, which is a third-party non-governmental organization that establishes and maintains technical standards for the construction and operation of ships and offshore structures. Presently the main classification societies in the world include: Lloyd's Register (LR, England), Bureau Veritas (BV, France), Registro Italiano Navale (RINA, Italy), American Bureau of Shipping (ABS, USA), Det Norske Veritas & Germanischer Lloyd (DNV GL, Norway), Nippon Kaiji Kyokai (NKK, Japan), Russian Maritime Register of Shipping (RS, Russia), China Classification Society (CCS, China), and Korean Register of Shipping (KRS, Korean).

In addition, some design rules or standards developed by international or national organizations, committees, and industry associations are also commonly used, e.g., ISO, IEC, Eurocode, NORSOK, etc.

The present chapter mainly addresses rules and standards related to structural design of ocean energy devices. The substructures for offshore wind turbines, wave energy converters, and tidal energy converters are considered.

Design Optimization

► Optimal Design

Design Rules and Standards

Wenbin Dong

Senior Engineer Technical Advisory of Offshore Structures, DNV GL AS, Høvik, Oslo, Norway

Introduction

A design rule or standard for marine structures provides principles, technical requirements, and guidance for the structural design and the design verification of load-bearing structures subjected to foreseeable actions in marine environments. A design verification represents the confirmation for compliance of a structural design with defined requirements. Marine structures usually include ship structures and offshore structures. When designing a unit where an object standard exists, the object standard for the specific type of unit shall be applied. The main objectives of a design rule or standard are to:

- Provide an internationally acceptable level of safety by defining minimum requirements for structures and structural components (in combination with referred standards, recommended practices, guidelines, etc.)

Design Rules and Standards for Offshore Wind Turbines

The integrated design of an offshore wind turbine and its substructures is in its growth stage.

Reducing its levelized cost of energy (LCOE) is still challenging. How to match the design methods for wind turbines' aerodynamic load & response and the design methods for conventional offshore structure, and refine them, are the key issues for a successful design of offshore wind turbines.

Presently the designer can essentially rely on the following standards/technical specifications for the design of bottom-fixed offshore wind turbines and their substructures:

- IEC 61400-3 (IEC 2009)
- DNVGL-ST-0126 (DNV GL 2018a)
- DNVGL-SE-0441 (DNV GL 2016a)
- ABS #176 (ABS 2013a)

and for the design of floating offshore wind turbines and their substructures:

- DNVGL-ST-0119 (DNV GL 2018b)
- DNVGL-SE-0441 (DNV GL 2016a)
- ABS #195 (ABS 2013b)
- BV NI 572 (BV 2015)
- ClassNK Guideline (ClassNK 2012)

Although there exist design standards for floating wind turbines, the industry is still in an early stage of development; therefore further development and revision of these standards is necessary when the relevant industry experience is available.

The most common rules to certify offshore wind turbines are the IEC 61400-3 rule and the DNV-GL guidelines. The current edition of the IEC 61400-3 rule considers bottom-fixed offshore wind turbines. In addition, a draft technical specification of IEC TS 61400-3-2 (IEC 2018) for the design of floating offshore wind turbines has been published by IEC, where the first edition of the technical specification will be published in the near future.

DNVGL-ST-0126 is the latest version of the DNV GL standard for guiding the design of support structures of wind turbines, which supersedes the May 2014 edition of DNV-OS-J101 (DNV 2014) and the April 2016 edition of DNVGL-ST-0126. The standard is applicable to all types of onshore and fixed offshore support structures

for wind turbines as shown in Fig. 1. It takes construction, transportation, installation, and inspection issues into account to the extent necessary in the context of structural design. Design loads and load combinations to be considered together with this standard shall be determined as described in DNVGL-ST-0437 (DNV GL 2016b). It does not cover design of support structures for substations for wind farms and design of wind turbine components such as nacelle, rotor, generator, and gearbox. For design of support structures for substations, such as converter stations and transformer stations, DNVGL-ST-0145 (DNV GL 2016c) applies. For structural design of rotor blades, DNVGL-ST-0376 (DNV GL 2015a) applies. For structural design of wind turbine components, DNVGL-ST-0361 (DNV GL 2016d) applies.

DNVGL-ST-0119 is the latest version of the DNV GL standard for guiding the design of the support structures and station-keeping systems for floating wind turbines, which supersedes the June 2013 edition of DNV-OS-J103 (DNV 2013). The standard is applicable to all types of support structures and station-keeping systems for floating wind turbines. Figure 2 shows four common floater types for wind turbines. It gives provisions for the floater motion control system and the control system for the wind turbine to the extent necessary in the context of structural design, no matter these systems are separate or combined. It also gives provisions for transportation, installation, and inspection to the extent necessary in the context of structural design. It does not cover design of wind turbine components such as nacelle, rotor, generator, and gearbox. For structural design of rotor blades, DNVGL-ST-0376 applies. For structural design of wind turbine components for which no DNV GL standard exists at present, the IEC 61400-1 standard (IEC 2005) applies.

DNVGL-SE-0441 is a new service specification for type and component certification of onshore and offshore wind turbines. The certification scheme is aligned with the IEC 61400-22 (IEC 2011) scheme for the technical requirements and the certificates. This specification together with referred DNV GL standards and recommended practices represents a completely revised and

Design Rules and Standards, Fig. 1 Definition of wind turbine components (DNV GL 2018a)

Design Rules and Standards, Fig. 2 Four common floater types for wind turbines (DNV GL 2018b)

expanded version of GL-IV-1 (GL 2010) and GL-IV-2 (GL 2012), both with a history of 30 years. It applies to type certification of wind turbines as well as for component certification.

The development for most of the other standards, both national and international, has been aligned with IEC 61400-1 and 61400-3. For example, ABS #176, also an international standard, issued first in 2010 and revised in 2013, is mostly aligned with IEC 61400-3. ClassNK published “Guideline for Floating Offshore Wind Turbine Structures” in July 2012, which applies to unmanned floating structures with a 20-year design life or over and to the tower and rotor nacelle assembly (RNA) as options. The guideline was developed referring to IEC 61400-1 and IEC 61400-3 and the related ClassNK Rules for the Survey and Construction of Steel Ships. The design principle provided in the guideline is to maintain the structural integrity of floating structures throughout their design lifetime without the need for docking and repair, and to consider the absolute minimum of damage stability and one line breaking in order to prevent drifting.

Design Rules and Standards for Wave Energy Converters

Presently there are no rules or standards for the structural design of WEC devices; however the rules, standards, and guidelines existing within the offshore engineering are useful for the design of WECs.

Design of wave energy converters (WECs) is still in its infancy, when compared to wind turbines, solar panels, and even tidal turbines, so it faces significant hurdles to achieve commercial applications. Different concepts are being investigated with different stages of development in the world, which range from concepts to full-size prototype devices and early commercial units. It is common that each WEC has its own method of operation, resulting in different amounts of power production in different wave patterns. In addition, it should be noted that WECs generally differ from other renewable energy devices in terms of the relation between maximum power output and average power output. Specifically, under design environmental conditions, wind, tidal, or solar

power devices will produce consistent power at their rated maximum, while for WECs the average power production will generally be much less than the maximum rated power. This can be misleading to estimate the annual power output for a WEC through the rated power. Up to now, most device developers of WECs rate their devices through the maximum power output (SI-Ocean 2012).

In order to assess the different technologies on a level playing field to allow for a fair and standardized comparison, and develop a uniform method to evaluate both a WEC and the location of installation for different sectors of the industry, the establishment of standards is important for WECs development, and significant efforts are currently underway. Several international collaborations have been initiated to establish rules and standards for rating the power of WECs, which should lead to standardized methodologies for assessing different devices so that fair comparisons can be made. Moreover, guidelines, rules, and standards should also provide detailed procedures and methodologies for design, testing, and operation of wave energy converters.

The International Electrotechnical Commission (IEC) established the Technical Committee (TC) 114 on Marine Energy: Wave, Tidal and other Water Current Converters in 2009. Through a collaborative international effort, a set of new technical specifications (precursors to standards) for the emerging field of marine energy systems have been published since 2011, and more tasks are being carried out by the IEC-TC-114 (2014). Two most advanced technical specifications (TS) for resource assessment and mooring system of WECs were published in 2015:

- IEC TS 62600-101 (IEC 2015a)
- IEC TS 62600-10 (IEC 2015b)

CarbonTrust (2005) commissioned DNV GL for preparing a “guideline on design and operation of WECs” in 2005. The main objective of this document is to provide interpretation and guidance on the application of the various existing standards and guides to WECs devices and it included many aspects on design and operation of WECs. It should be noted that this document

should be regarded as a guideline instead of a standard.

DNV (2008) published the principles and procedures for certification of tidal and wave energy converters in 2008 and made two amendments in 2011 and 2012. The document is built on experience and relevant standards in the oil and gas industry, but also includes the best practices in this particular area. It is supposed to cover all types of tidal and wave energy converters.

In general, the technologies for wave energy conversion are still immature, and many devices are in different stages of development, while new concepts are continuously being proposed. To guide the rational development of WECs, some best practices have been recommended. Unlike the standards, the best practices are regarded as guidelines on how to transfer WECs from the concept stage to the commercial application, and avoid the most common failures.

The design basis and the cost basis for wave and tidal energy systems are discussed in a document entitled “Development of Recommended Practices for Testing and Evaluating Ocean Energy Systems, Summary Report” published by Nielsen (2010), which follows the Implementing Agreement for a Co-operative Programme on Ocean Energy Systems (OES-IA) created by the International Energy Agency, Annex II. Similarly, many deliverables from the EquiMar project have been published on its website <http://www.equimar.org/>, where two of the deliverables with the topics “Best Practice for Tank Testing of Small Marine Energy Devices” and “Protocols and Guidance for Device Specification and Quantification of Performance” may be more relevant for WECs. Other relevant information can also be found from the MariNet project (http://www.fp7-marinet.eu/joint-activity_standardisation_best-practice.html) and the EMEC website (<http://www.emec.org.uk/standards/>).

Design Rules and Standards for Tidal/Ocean Current Turbines

The development of the technologies for tidal/ocean current turbines falls between that of offshore wind turbines and that of WECs, where a

full commercialization is possible. The commercial impacts on developers become greater as the size of turbines and scale of planned arrays increase. Therefore more attention is paid to the reduction of risk and the processes through which risk is controlled and mitigated, which should be the core in the development of new standards/technical specifications (TS) in the future. In addition, a clear structure and guidance on how to move from prototype through to type and project certification should be also set clearly in new standards/technical specifications, keeping the elements of the risk-based approach used in technology qualification and their earlier editions.

Presently the designer can essentially rely on the following standards/technical specifications for the design of tidal/ocean current turbines and their substructures:

- IEC TS 62600-201 (IEC 2015c)
- DNVGL-ST-0164 (DNV GL 2015b)
- DNVGL-SE-0163 (DNV GL 2015c)
- BV NI 603 (BV 2013)

Although there exist design standards for tidal/ocean current turbines, the industry is still in an early stage of development; therefore further development and revision of these standards is necessary when the relevant industry experience is available.

IEC TS 62600-201 is a new technical specification (TS) published by IEC Technical Committee 114 (IEC TC-114) in 2015. It concerns methods and procedures for determining, objectively and reliably, the scale and character of the tidal energy resources in a region. The documentation is intended to become international standard, once sufficient industry experience in its application has been developed.

DNVGL-ST-0164 is a new DNV GL standard for guiding the design, construction, and in-service inspection of tidal turbines. The documentation covers design and construction of structures (including blades, rotor, nacelle, supporting structure, and foundations), machinery, safety, controls and instrumentation, and electrical systems. It takes transportation, deployment, retrieval, and inspection issues into account to the extent necessary

regarding their impact in the design and construction aspects.

DNVGL-SE-0163 is a new service specification for prototype, type, project, and component certification of tidal turbines or tidal turbine arrays. It replaces the DNV GL standards DNV-OSS-312 (DNV 2008) on the tidal subject and GL IV-14 (GL 2005) on the ocean current turbine subject. The documentation covers all types of turbines and their support structures, fixed or floating, and all types of substation (s) including support structure(s), power cables, and subsea connectors. It also covers the project certification of an array of tidal turbines.

Generally, the technologies of tidal/ocean current turbines are becoming mature. The commercial impact on developers will play an important role in the future. The key to further development of the industry is the reduction in cost and the control of risk. For tidal turbine developers, the new standards/technical specifications should provide a clear scope for type certification which is key to open up commercial opportunities for volume production. Project developers themselves will be interested both in what a “type-certified” turbine means but also in certifying their own projects to satisfy their investors and insurers that they have controlled their risks, which should be also reflected clearly in the new standards/technical specifications.

design; Sequential engineering; Technical design

Definition

Design spiral mostly describes the construction process of submersible design, including AUV, ROV, HOV/HROV, ARV/MS, Glider, Deep Tow

System, Lander, ADS, DSRV, Rescue Bell, and Deep float design. Design spiral is often used in preliminary design process of submersible up to submersible tender. It elaborates sequence of design steps and uses sequential cyclical approach and iterative process with increasing complexity to result in single feasible submersible with economically reliable tender. It is rule-based and is subject to univariate systematic variation with constraints.

Scientific Fundamentals

Basic Definitions About the Design Process

Evans introduced the concept of design spiral in 1959, which represents the sequential and iterative aspects of the process.

Spiral is used to depicts sequential, cyclical decision process, which uses Class rules as basis and can result in optimal, low weight submersible structure. At every intersection of a spoke with a spiral, a calculation must be performed to update the structure, thus can lead to a feasible design. In the early stage of submersibles design, spiral is often used. It elaborates sequence of design steps and uses sequential cyclical approach and iterative process with increasing complexity. Spiral design is an iterative process, which is rather difficult to capture in a model. The design spiral in Fig. 1 is a traditional way of “capturing” the ship design process. As the design progresses, it converges to a single point. Each baseline is a new iteration of the design.

Many of the (largely iconographic) representations of the preliminary ship design process,

Design Spiral, Fig. 1 An early typical design spiral (Evans 1959)

such as those in the 2009 IMDC report, show the iterative nature of that process, which is seen as one of the advantages of the design spiral representation. This iterative characteristic even applies to most of the other, largely sequential, representations of the process. This feedback process can be seen in both the classical sequential ship design synthesis (Fig. 2) and in the more

integrated approach behind the DBB approach adopted. From the 12th preliminary ship design representation in the 2009 IMDC SoA design methodology report, that in both the numerical sequential and the architecturally integrated (DBB) representations the output is fed back to the input, once a ship design balance has been achieved. This reconsideration of the input

Design Spiral, Fig. 2 A simple numeric ship sizing iterative sequence with feedback (Andrews and Dicks 1997)

(requirements) is entirely consistent with the preferred systems engineering approach of Requirements Elucidation propounded by the second author (Andrews 2012). So there is both feedback at a gross level of the whole ship design process, which is often seen to be consistent with achieving one revolution of the design spiral, but this is also seen to occur at each component step (such as the purely numerical balance of weight and space of Fig. 3). These are subtleties not easily modelled by a single design spiral.

The other aspect that the design spiral is considered to model, or at least acknowledge, is the interactive nature of ship design. This is said to persist through out the process, such that any change in a subcomponent system has knock on effects across a range of other supporting ship systems. Thus simply in sizing fuel tanks on a naval ship, Rawson and Tupper's classic text book (1976) shows what is called a "design influence diagram" to reveal the influence on both the preliminary sizing and the final fuel tank arrangements. So changes in anyone of the influences will lead to alterations in this set of fuel tanks. Thus there are a host of interacting consequences with most of the ship design variables being interdependent to a significant degree. The set of tanks will then themselves have influences on, typically, the stability of the ship requiring changes to ship dimensions, weight balance, and structural scantlings, which will further alter the design downstream across a whole range of other component subsystems.

Thus these two aspects of ship design, the iterative and the interactive, need to be reflected in any model or representation of initial ship design, such as the design spiral, if it is to be a valid representation of the ship design process. In particular, such representations should indicate how a design evolves due to major changes in requirements or choices in design style in order to achieve a balanced design.

Basic Introduction to the Process of Design Spiral

Perhaps the most comprehensive representation of the ship design spiral is that reproduced at Fig. 4, due to Rawson (1986). This has 27 steps round the spiral, since it includes the set of "prime"

and "additional" hull form parameters, that he considers to be determined in the process. Furthermore, this spiral reverses the usual spiraling inwards to a solution by spiraling outwards, perhaps suggesting the increase in complexity of the solution as it evolves but still (hopefully) converges? Each sweep is said to be a major phase of the whole ship design process, namely, economics, military effectiveness (these cover commercial and naval vessels respectively), concept, feasibility, and finally full design.

A three-dimensional picture of the design spiral, as a tapering corkscrew, for each of the major ship design phases was done to emphasize, unlike the two-dimensional representation with a progressive sequence of closed loops, that real ship design operates with considerable dialogue in and out of the looping process with inputs by the designer and the many stakeholders (Fig. 5).

This 3-D model was intended to describe (any) one phase of the ship design process and as such could require several complete spirals to achieve the appropriate design balance. This model was felt to be consistent with the description of the concept phase and also with the subsequent feasibility phase undertaken after the concept phase and prior to approval to contract for detailed design and construction. The second author has managed projects with year long feasibility studies, which were only considered to be complete after three full cycles of design balance, each of increasing design fidelity.

Thus strong interactions are suggested throughout the spiraling process with a series of external influences or constraints. These constraints were described as respectively:

- Directly on the design – seen as direct impositions from the customer/users/specialists/classification societies, for aspects such as reduced manning.
- On the design process – such as sources of design data and tools/methods/standards, which might well alter the spiral sequence and lead to the process jumping back and forth, also some of these can be influenced by the design team.
- Originating from the design environment – these are wider constraints, such as the

ASSUMPTIONS

Final ship design solution will not demand major equipment changess

The level of complement machinery, services, structure etc. will be in line with current solutions

The degree of complexity, structural philosophy, standards of accommodation, upkeep, margin philosophy implied

Conventional wisdom on form parameters, shafting, machinery redundancy, etc.

Level of operation (endurance), maintenance philosophy, navy or company manning philosophy and organizational structure

Systems operating and upkeep philosophies, redundacny, etc.

Applicability of hydrodynamics data (triplet, methodical) series), usage of auxiliaries, philosophy on tank allocation (Stability, longitudinal balance, proximity)

Assumed structural design philosophy and material choice, implied configuration solution (% access), design point, stability philosophy

Judgement of 'Satisfactory Balance'

STEPS IN PROCESS

Payload

Total internal volume

First shot at displacement

Selection of machinery

Complement

Auxiliary power and services

Tank volume

Overall displacement and internal volume

Reiterate until displacement and volume balance

SOURCES

Historical data on equipment or estimates by equipment designers (weight, space, services, complement)

Based on past practice from payload volume

Measures of the density of the current ships of that category

Power/speed/displacement plots
Machinery data (volume, mass, auxiliary power, complement)

Either overall figure displacement dependant or given by the sum of complement for machinery, payload and remainder

Equipment data
Data book of historical demand related to ship size complement with step changes for discrete range of equipment

Endurance calculation (hydrodynamics data).
Hotel fuel consumption
Fresh water, lub oil, voids

Sum of payload, mcy, services outfit, structure
Margins on items, growth, 'Board'
Superstructure volume as proportion

Design Spiral, Fig. 3 Design spiral (Evans 1959; see Taggart 1980)

Design Spiral, Fig. 4 A ship design process model (Rawson 1986)

Design Spiral, Fig. 5 3-D representation of the ship design spiral (Andrews 1981)

education and training of the designers, government legislation (e.g., environmental/safety), economic climate, major organizational changes, all of which can be highly influential but over which the design team has no influence.

Having remarked that the design spiral takes many forms in trying to represent a complex process, it is now appropriate to consider nonlinearity in the evolution of most ship designs and whether this fact limits the value of the design spiral in modelling the design process.

Historical Development of Design Spiral

The first use of the design spiral in ship design is usually attributed to Harvey Evans (1959) in outlining the sequence for midship structural section design. His spiral has nine steps that were shown to be repeated several times – hence the spiral representation, as shown in Fig. 6.

This example was followed by several versions representing the whole ship design process

(such as the second, third, and ninth examples reproduced in the 2009 IMDC SoA design methodology report (Andrews et al. 2009)). These show the same steps being undertaken at each sweep of the spiral (but clearly each time more comprehensively). Rawson and Tupper (1973) even remark that not all the twelve steps, which they show, “are required to be developed in depth at every iteration.”

Several years later, in 1965, in order to get reliable cost estimate, MarAD Proposed a preliminary design spiral shown in Fig. 7. It takes sequential, cyclical approach in rigid sequence, which is based on rules and takes univariate systematic variation with constraints. Thus result in single feasible ship with lowest building and fuel cost.

It is considered debatable whether each of the above major design phases should be shown as only one sweep. Eames and Drummond (1977) (the fifth example in the 2009 SoA design methodology report) in their concept exploration paper show three concept

Design Spiral,

Fig. 6 Midship section structural design diagram

Design Spiral, Fig. 7 Preliminary design spiral (MarAD 1965)

stages, each as a complete sweep (called “concept exploration, concept development, and concept validation”) and with ten steps or “spokes.” These follow the same sequence for each of their concept stages and the process starts with a “basis ship” (rather than even outline requirements) and ends with “contract design.” The latter suggest this is modelling a process typical of a commercial shipyard’s bid response to a ship owner’s indicative design, rather than the more protracted concept phase for naval procurement. An example of the latter was outlined for UK warship procurement (Andrews 1994) with three overlapping stages entitled concept exploration (but quite different to the Eames and Drummond (1977) usage, being much more divergent), concept studies and concept design, all undertaken prior to what is now known as the Initial Gate decision point in the UK Ministry of Defence (UK MoD 1999). It is

also relevant that each of these concept stages do not follow the simple repetitive description of the design spiral, as the 1994 paper demonstrates.

A further variant on the representation of the design spiral was proposed in 1981 by Andrews (see Fig. 5, the sixth example in the 2009 IMDC SoA design methodology report). This gives a three-dimensional picture of the design spiral, as a tapering corkscrew, for each of the major ship design phases.

Key Applications

Design spiral has been used in many areas such as ship design, sequential engineering, ROV design, AUV design, preliminary design, etc. Here we list two most important use.

Ship Design

The process of ship design has an iterative nature that is most commonly described by a design spiral that reflects the design methodology and strategy.

The goals for the ship design are not the same for all ship-owners; NAP (Naval Architecture Progress) developed the tools and gained the experience to incorporate all different – conflicting requirements and expectations in its design mission.

The design spiral shown in Fig. 8 shows interactions between different areas whose iterations and trade-offs need to be converged to a baseline. However, the spiral does not show the interaction between the engineering areas as iterations progress. These interactions are shown in Fig. 9. The design has an overall spiral, shown in the orange arrows. Within the spiral, there are internal spirals (yellow arrows) which represent the different engineering groups iterating their own work in that iteration's baseline.

Design Spiral, Fig. 8 Ship design and construction (Thomas Lamb 2003)

Design Spiral, Fig. 9 Ship design spiral

Arrows in the process viewed in Fig. 9 show major information flow. While the arrows capture some of the design interaction, all of the iteration that needs to take place cannot be detailed in a process mode.

ROV Design

Today, with the aid of advanced computer design techniques, the modern ROV has evolved through many iterations of the design spiral shown previously. Today's ROVs are relied upon to perform complex operations offshore, in ever increasing water depths, and have accordingly reached a high level of technical design. These vehicles must also be flexible, that is, they must be capable of being configured for many tasks. This holds true for small and large systems, which are used for a variety of inspection and/or work tasks. Since the goal of the ROV is to accomplish an often-complicated task, its overall capability is usually driven by two major considerations – work requirement and operational water depth – both of which drive the considerations of the design spiral.

The ROV system is a highly interrelated group of subsystems that, when functioning

synergistically, provides an impressive subsea capability. Since the characteristics of the vehicles are multivariant, with no unique solution, the design process is necessarily iterative. Because of this highly interdependent relationship, ROV system performance is a delicate balance of design and operational characteristic tradeoffs. The system can be arbitrarily divided into a number of major subsystems. These would generally include:

- Vehicle
- Tools and sensors
- Control/display console(s)
- Electrical power distribution
- Umbilical and tether cables
- Handling system

The interrelationship of such subsystems is graphically illustrated in the “design spiral” shown in Fig. 10, the following figure. For example, an operator may desire a modest increase in the speed capability of an ROV to maneuver in a current condition in a particular geographic area. The additional speed desired will result in the need for additional electrical energy and may

Design Spiral,

Fig. 10 ROV design spiral

generate the need for changes in the thruster/pulsation subsystem. Additionally, the configuration, structure, weight, control system, umbilical/tether size, tether management system, winch, handling system and power supply will all be affected.

Clearly, all of these subsystems and components are affected by what was a seemingly innocuous performance improvement desire. Thus, the designer or user/operator is well advised to be aware of the ROV system's sensitivity to change and carefully consider the serious ramifications of contemplated changes to what may appear to be minor components. The desire for small improvements in performance or the failure of a "minor" component will often have ripple effects through the entire system.

Definition

Detailed design is the last stage of technical design and it completes the design of the performance, structure, electrical, materials, components, processing, assembly and testing of the submersible system, and forms a complete set of technical design documents and drawings, which can be used as the basis for the next construction, integration, and test.

Scientific Fundamentals

Basic Introduction to the Design Process

The design and associated processes are diagrammed in Fig. 1 in a chronological order as (1) pre-design, (2) design, and (3) post-design processes (Allmendinger 1990). In this section, they are introduced briefly from the perspective of the mission system to provide an overview of the entire subject.

The pre-design process leads to the formulation of the basic input to the design process, that is, the mission(s) statement(s) and associated mission *requirements*. It is undertaken by the potential user or owner of the mission system to be designed, independently or in consultation with the system's designer.

The design process is composed of three design phases: (1) *basic design*, (2) *contract design*, and (3) *detail design*. The levels of labor, preparation time, and costs associated with each phase increase exponentially as the process progresses. Design creativity and flexibility are essentially limited to the basic design phase – the mission system, including its submersible system, being well defined at the beginning of contract design.

The post-design process is composed of three activities: construction/alteration, test and evaluation, and operation. Although this publication is not directly concerned with these activities, there are two reasons for including them in this overall perspective: (1) They constitute important sources of input to new designs and feedback to the design in question, and (2) they are subject to certain existing MEDCs and will influence the future impact of MEDCs on following designs.

Conceptual design is the first attempt to translate all the user/owner's mission requirements into performance requirements and characteristics of the systems composing the mission system. It is often viewed as consisting of *feasibility studies* and *completion of the optimum conceptual design(s)* once they are identified by these studies. Feasibility studies are concerned with the development of those performance requirements and associated system characteristics which have significant impact on the cost-effectiveness optimization process. Completion of the optimum

design(s) involves developing other major performance requirements and characteristics those which are essential in defining systems but which do not have significant impact on the optimization process.

Preliminary design is the second stage of the basic design and is concerned with this phase's fifth function. Starting with baseline data provided by the selected conceptual design(s), it refines and firms up the major characteristics of systems, the MIDCs they exert on each other, and cost estimates associated with them. In summary, it provides a precise engineering definition of the mission system and assurance that the design goal can be attained.

Contract design requires yet further refinement of design and additional detail. It yields contract plans and specifications necessary for interested parties to bid on the construction of new systems or the alteration of existing systems. It also provides contractual documents for the construction and alteration work.

Detail design is the final phase of the design process and entails the development of detailed working plans from which the systems are constructed or altered. In one sense, it is really not a design phase since all the creative design effort is done in the preceding phases, the design being unequivocally defined prior to entering this phase. It does, however, require the greatest amount of work of all the phases and is often undertaken by entities building or altering the system.

Basic Introduction to the Design Spiral

The iterative nature of the overall design process may be modeled by the design spiral shown in Fig. 2. The spiral consists of spokes and loops. The spokes represent design considerations including performance requirements, submersible characteristics, and cost estimates; submersible characteristics are embodied in its arrangement, geometry, six SWBS systems groups, and summaries of energy requirements and weight/displacement centers. The loops indicate design iterations with design's refinement increasing as the loops spiral inward. Outer loop procedures use empirical formulations and estimates based on

Detailed Design, Fig. 1 Design and associated processes (Allmendinger 1990)

Detailed Design, Fig. 2 Design spiral (Allmendinger 1990)

similar design data, whereas middle and inner loop procedures are based on progressively more detailed development of the design considerations utilizing increasingly precise formulations. The intersection of spokes and loops forms points which are identified alphanumerically. Thus, for example, 3B is a point in the spiral at which the geometric characteristics of the submersible are being considered in the second iteration in a more detailed manner than they were initially at point 3A. At 3B, adjustments are made as the result of both the more detailed consideration of the geometric characteristics required and the impact on

geometry of interrelated design considerations for which data were generated at points in the spiral preceding 3B. Adjustments are made at other points in the spiral for the same reasons. For the design to converge to a satisfactory solution of the design problem, these adjustments must become progressively smaller with each succeeding loop through conceptual, preliminary, and contract design. This fact is demonstrated on the spiral by the decreasing spacing between loops as they spiral inward. Convergence is illustrated by the innermost loop becoming a circle, indicating that all design considerations are fully developed and

require no further adjustments. At this point in the spiral, detailed design can begin.

Take the loop A for example:

- 1A. Performance Requirements: Derive performance requirements from the mission requirements pertinent to the submersible's design. These performance requirements should include depth, range, speed, maneuvering, personnel on board, endurance, payload, system requirements, safety features, and limiting sea states.
- 2A. Arrangement: Initially, the submersible may be considered as consisting of the pressure hull (s), envelope, and all other items comprising it. Select types and number of pressure hulls, type of envelope, and location of major items of SWBS system either inside or outside the pressure hull.
- 3A. Geometry – shape and dimensions: Obtain first estimates of pressure hull and envelope geometry and volumes and displacement of submersible.
- 4A. Hull Structure: Fixed ballast and buoyancy are included in this group – these systems have the function of providing for neutral buoyancy, zero trim, adequate stability, and a weight margin in design. At this point, only the amount of fixed ballast for the last function is included, its weight is usually 10% or less of the total displacement. Fixed ballast or buoyancy serving other functions is considered at Point 11, weight displacement center summary.
- 5A. Propulsion Plant: The propulsion power source – which consists almost always of batteries for untethered submersibles – is included in this group. However, for convenience, consideration of this system's sizing data is deferred until Point 10, energy summary.
- 6A. Electrical Plant: The non-propulsion power source for auxiliary and other system's service loads is included in this group. Again, for convenience, consideration of this system's sizing data is deferred until Point 10. The remaining systems of this group, the power distribution and lighting systems, constitute very small percentages of Condition A1 (light ship minus fixed ballast/buoyancy) weight and displacements. Consequently, first estimates of weight and displacement of this group, excluding non-propulsion power source, may be obtained using percentages from similar design data.
- 7A. Command and Surveillance: The total weight and displacement of this group of systems are also very small percentages of Condition A1 weight and displacement. As at Point 6A, first estimates of this group's weight and displacement may be obtained using percentages derived from similar designs.
- 8A. Auxiliary Systems: Certain systems in this group require comment. The auxiliary systems include human system, air gas and miscellaneous fluids systems, static control systems, dynamic control systems, and mission systems.
- 9A. Outfit and Furnishings: This system's weight and displacement are minute percentages of the Condition A1 weight and displacement. In both instances, 1% may be used for first estimate purposes. Space requirements are another matter for items inside the pressure hull, ladders, lockers, hull insulation, seats, and so forth. Even first estimates of these sizing data should be made with great care because they have considerable influence on pressure hull volume and, hence, have a cascading effect on other design considerations.
- 10A. Energy Summary – Energy Storage Systems: At this point, the power-energy requirements for the SWBS systems should be summarized and the sizing data for the electrical and pneumatic energy storage systems estimated, the two forms of energy carried on board almost all untethered, manned submersibles. The summarization procedure for electrical energy storage systems, assumed to be secondary batteries, involves use of a power energy profile.
- 11A. Weight Displacement Center Summary: At this point, summarize weights and displacements of SWBS systems and their loads and achieve the submerged design condition criterion of neutral buoyancy, in which total weight and displacement are equal. Note that the other two design condition criteria of zero trim and adequate positive stability are addressed at Point 11B when estimates of longitudinal and vertical centers of weight and displacement are available.

12B. Cost Estimate Summary: Summarize estimates of first and annual operating costs associated with the SWBS systems selected for a particular design alternative.

Key Applications

Development of Deep Sea Manned Submersible

Manned submersible is an important technical means and equipment for deep sea entry, exploration, development, and protection, which represents the development frontier of the submersible technology. Alvin was the most famous (Kaharl 1990; WHOI 2018) while other large depth manned operational submersibles include Nautile of France (Lévêque and Drogou 2006); MIR I & II of Russia (Sagalevitch 2009); Shinkai6500 of Japan (Takagawa 1995); and Jiaolong of China (Cui 2013).

In 2002, China launched the development of the 7000 m manned submersible Jiaolong. Through the joint research of nearly 100 dominant scientific research institutions in China, through the stages of scheme design, preliminary design, detailed design, processing and manufacturing, general assembly and commissioning, and functional test of water tank, the technical conditions for sea trial were met in early 2008.

From August to October in 2009, May to July in 2010, July to August in 2011, and June to July in 2012, the sea trials tests of 1000, 3000, 5000, and 7000 m were completed, respectively, and the

maximum diving depth reached 7062 m. In 2013, 7000 m manned submersibles have been put into use. More than 150 dives have been completed in the South China Sea, the manganese nodule area in the eastern Pacific Ocean. The cobalt-rich crust areas are in the Western Pacific Ocean, the Mariana Trench, the southwest Indian Ocean, and the northwest Indian Ocean. A large number of biological, mineral, sediment, and rock samples have been obtained, and the high-resolution image data of the seabed have been taken, which provides a basis for the assessment of deep-sea resources and environment important basis. In 2019, the first test dive will be completed after major repair and technical upgrading (Hu and Cao 2019) (Fig. 3).

Alvin Upgrade

Alvin is the world's longest-operating deep sea submersible. It was launched in 1964 and has made more than 4700 dives, along the way participating in some of the most iconic discoveries in the deep ocean. Throughout 2011, 2012, and into 2013, *Alvin* received a comprehensive overhaul and upgrade funded by the National Science Foundation that greatly expanded its capabilities and will eventually put almost the entire ocean floor within its reach.

The upgrade is taking place in two stages. After Stage 1 was completed in 2013, *Alvin* boasted several new improvements, including: (1) A new, larger personnel sphere with an ergonomic interior designed to improve comfort on long dives. (2) Five viewports (instead of three) to

Detailed Design,

Fig. 3 Jiaolong deep manned submersible (www.cssrc.com)

Detailed Design,**Fig. 4** Alvin upgrade
(www.whoi.edu)

improve visibility and provide overlapping fields of view for the pilot and two observers. (3) New lighting and high-definition imaging systems. (4) New syntactic foam providing buoyancy. (5) Improved command and control system.

Several of these and other improvements to the sub have been designed to withstand descents to 6500 m – the remainder will be upgraded later. As a result, Alvin will initially maintain its current depth rating of 4500 m. In Stage 2, the entire sub will be upgraded to 6500 m depth. In addition, new batteries will be introduced to enable the submersible to stay at depth longer, giving scientists more time to work in unexplored parts of the ocean and putting 98% of the seafloor within their reach (Fig. 4).

New Technology Development

Titan is a Cyclops-class manned submersible designed to take 5 people to depths of 4000 m (13,123 feet) for site survey and inspection, research and data collection, film and media production, and deep sea testing of hardware and software. Through the innovative use of modern materials, Titan is lighter in weight and more cost efficient to mobilize than any other deep diving submersible. A combination of ground-breaking engineering and off-the-shelf technology gives Titan a unique advantage over other deep diving subs; the proprietary Real Time Hull Health Monitoring (RTM) systems provide an unparalleled safety feature that assesses the integrity of the hull throughout every dive. The use of off-the-

shelf components helped to streamline the construction, and makes it simple to operate and replace parts in the field.

Paired with a patented, integrated launch, and recovery platform, Titan is easy to operate in varying sea states using a local appropriately sized ship for the project. In coastal waters this means we do not need a large support ship with a crane or A-frame.

Diving of Anchors

Yinghui Tian
Department of Infrastructure Engineering,
The University of Melbourne, Melbourne, VIC,
Australia

Introduction

The word of “anchor” derives from the Latin form of ancora, where, in a broad sense, anchor is a type of device to stabilize structures, including the offshore anchors as well as soil nails to reinforce

foundations, retaining walls, and slopes. This entry concentrates on the fully embedded offshore anchors, e.g., traditional fluke anchors or more recently plate anchors, used to connect a floating offshore structure to the seabed to prevent it from drifting due to wind, wave, or current.

Floating offshore structures including vessels, drilling rigs, and platforms are subjected to large environmental forces, and most rely on permanent or temporary anchoring systems to withstand these forces. Some of these floating systems, such as floating production storage and offloading (FPSOs) vessels and floating production systems (FPSs), are normally required to remain on station for long periods, while mobile floating systems, such as mobile offshore drilling units (MODUs), use anchoring for temporary mooring to withstand the severest weather conditions. The performance of anchors embedded in the seabed therefore has a great influence on the reliability, integrity, and operational safety of these floating systems. Anchors embedded in the seafloor generate their holding capacity mainly by mobilizing the shear strength of the soil to resist the pulling force. Therefore, the digging or diving depth of anchors is a critical factor to determine the holding capacities of embedded anchors.

Encouraging Anchors to Dive

Anchor History

The evolution of anchors has a closely linked pace to the history of human civilizations, and the first anchor dates from time immemorial. From a chronological standpoint, the development history of anchors includes four distinct periods:

1. The prehistoric period associated with the use of stones to hold vessels by their weight. This kind of stone deadweight anchors were routinely used by the Egyptians.
2. The ancient period (Greco-Roman) when hook anchors first made of wood and gradually stiffened by metal parts were used. Chinese was reported to use hook anchors to stabilize bamboo stocks as early as 2000 BC.

3. The Middle Ages extending to the mid-nineteenth century characterized by a complete absence of innovations and even by the loss of certain attainments.
4. The present period started from 1821 marked by the extremely rapid development of techniques.

The patent for an anchor consisting of two flukes articulated about a pin perpendicular to the shank allowing diving and penetrating into the soil began this era. Along with this chronological line, some typical anchors are introduced as below.

Deadweight Anchors

The ancestor of all anchors is very probably a more or less flat stone pierced with a hole for the passage of a rope, as illustrated in Fig. 1a (Puech 1984). Although this primitive anchor idea was used from thousands of years ago, the mobilization of the holding force by means of a weight placed on the seabed offers such reliable results that this system is still used today in the form of deadweight weighing several thousand tons. Figure 1b shows the deadweight anchor on the North West Shelf of Australia for the guyed flare support tower at North Rankin, where a hollow box is placed on the seabed and then filled with rock and iron ore. Other similar application examples include those used in Wanaea and Cossack fields (Randolph and Gourvenec 2011).

However, this type of pure deadweight design is not efficient, as the resistance force is only a fraction of the weight to be handled. The evolution of anchor develops toward taking advantage of the seabed soil resistance. As illustrated in Fig. 1c, anchor stone fitted with wooden cross-pieces and killick use the combined action of weights and hooks designed to plow the seabed, which helped to increase the efficiency remarkably. The matching modern example is the innovative type of gravity anchor using a buried grillage, beneath a rock-fill or iron ore berm, which was used for the Apache Stag field development on the North West Shelf (Erbrich and Neubecker 1999). As shown in Fig. 1d, the grillage is placed toward the back of the berm but

such that the complete berm must be moved if the grillage starts to fail.

Hook Anchors

Hook anchors see a big step development toward taking advantage of the seabed soil resistance. The

earliest hook anchors consisted of an assembly of pieces of wood in a “V” shape, where a stone and a piece of bamboo were used by India and China as illustrated in Fig. 2a. The Greeks and Romans strengthened metal parts by stiffening the teeth or flukes with iron plates as shown in Fig. 2b. These anchors reached the summit of their development with the classic stock anchor, and the latest model

Fig. 2 Hook anchors

(a) Wood hook anchors

(b) Wooden hook anchor with stock and lead stiffeners

(c) Classic Admiralty anchor

of the type called the Admiralty Anchor (Fig. 2d) dated from the mid-nineteenth century.

The main feature of these anchors was undoubtedly that they derive their holding power

from embedding into sea floor. However, their efficiency was quite low due to the small fluke area penetrating into the seabed soil. The rapid increase in the weight of warships and

merchantmen in that time led to the development of stronger anchors with shanks and stocks 5–6 m long, which naturally became cumbersome and difficult to handle, despite the possibility of folding down the stock along the shank for stowing (Puech 1984).

Articulated Marine Anchors

Modern marine anchors were heralded by the Hawkins' patent in 1821 to stride to the era of modern articulated fluke anchors, which can be classified in two main categories: stockless anchors and stock anchors. Stockless anchors underwent rapid development to replace the hook-stock anchors in the end of the nineteenth century, which are still widely used today on warships and merchantmen. Figure 3a shows the “Union Universal” 20 t stockless anchor. Articulated stock anchors emerged slightly later with the stock located at the crown at the rear of the anchor as shown in Fig. 3b.

Special Anchors for Offshore Operations

The fast growth of offshore operations essentially related to petroleum exploration and production was accompanied by sweeping changes in anchoring requirements, due essentially to the steadily increasing size of the floating infrastructures. This led to the construction of stockless anchors and

stock anchors weighing up to 20 and even 30 t in air and arose to use anchor-handling vessels to install and retrieve anchors. Around 1970 some manufacturers and inventors, such Vryhof and Bruce tried to develop new products which were better adapted to offshore operating conditions. The spread of petroleum activities in the North Sea and Gulf of Mexico and the variety of soils encountered at the different sites are largely responsible for the huge innovative effort. Today, the evolution of anchoring techniques requires that the temporary mooring of supports mobilizing forces of ~200 t per anchor mooring line can be considered as a standard and reliable operation. Even better performing anchors are already capable of mobilizing forces of ~1000 t for the permanent anchoring of production supports.

Simplified Calculation Model for Embedded Anchors

The development of anchor holding capacity formulation involved empirical relationships related to anchor weight. For centuries, it appeared natural to mobilize resistance of the same order of magnitude as the submerged weight. The earliest investigations considering the surface area of the flukes as a significant parameter were conducted in the 1930s. The holding capacity, considered as the direct consequence of anchor-soil interaction,

(a) “Union Universal” 20t stockless anchor

(b) LWT 13t stock anchor

Diving of Anchors,**Fig. 4** Sketches of anchors

is expected to be more intimately related to the bearing area rather than the anchor weight itself.

Figure 4 shows the sketches of a traditional drag embedded anchor (DEA), a vertically loaded anchor (VLA) and a suction embedded plate anchor (SEPLA). The traditional DEA has a fixed fluke rigidly connected to a shank. The angle between the shank and the fluke is pre-determined, though it may be adjusted prior to anchor placement on the seabed. The DEAs have a limitation of taking large vertical loads, and thus the so-called vertically loaded anchors have been developed, where the slim-line shank can be reconfigured relative to the fluke following initial embedment (Murff et al. 2005). The SEPLA is inserted into the tip of a suction caisson, which is then used to penetrate the anchor to the required depth (Dove et al. 1998; Wilde et al. 2001). After retrieval of the caisson, the initially vertical SEPLA is preloaded by tensioning the mooring chain, forcing the anchor to rotate – a process known as “keying.”

For simplification purpose, the soil resistance on the anchor shank is neglected, and the above anchors may be idealized in a generic form as in Fig. 5, where e_n denotes padeye (normal to fluke) eccentricity (the shortest distance between padeye and anchor fluke) and e_p represents padeye (parallel to fluke) offset relative to the fluke centroid. Tian et al. (2014) proposed a definition of padeye offset ratio η as e_p/e_n and highlighted its influence on the tendency for the anchor to dive under load.

**Diving of Anchors, Fig. 5** Simplified calculation model**Analogous to Flying a Kite**

Although anchors seem to not have much connection to kites, the diving of anchor in soils can be interestingly analogous to flying kites in the air in terms of the mechanism. As shown in Fig. 6, there are four forces, i.e., lift N , weight W , drag S , and tension T_a , acting on the kite. Lift N is the upward force that pushes a kite into the air. Weight W is the downward force generated by the gravitational attraction of the Earth on the kite, which pulls the kite toward the center of the Earth. Tension T_a is the forward force that the line propels a kite in the direction of motion. Drag S is the backward force that acts opposite to the direction of motion. To launch a kite into the air, the force of lift N must be greater than the force of weight W . To keep a kite flying steady, the four forces are expected to be in balance.

The efficiency of a good kite is largely dependent on the line attachment point and the “attacking angle” that the line connects to the kite. This is essentially the idea of optimizing the padeye position and the offset angle in Fig. 5.

Diving of Anchors,

Fig. 6 The forces acting on a kite

D

Diving of Anchors, Fig. 7 The mechanism controlling anchor diving

Diving Mechanism of Anchors in Soil

Similar as the mechanism in flying a kite, the mechanism dictating whether an anchor dive or not can be shown in Fig. 7. The anchor is simplified as a rectangle with height B , thickness t , eccentricity e_n , and padeye offset e_p . The anchor width is denoted as L , which is the dimension perpendicular to the plane of Fig. 7. The anchor inclination, α , is the angle between the anchor fluke and the horizontal. The anchor effective weight, equal to the difference between the anchor

submerged weight and the soil buoyancy, is denoted as W' and is assumed to act at the anchor fluke. The effective weight is approximated as $(\gamma'_a - \gamma'_s) BLt$, where γ'_a and γ'_s are the submerged unit weight of anchor and soil, respectively. The chain pulling force at padeye is defined as T_a at an angle θ_a to the horizontal. The chain pulling force at mudline is denoted as T_m and the corresponding chain angle θ_m . The tension T_a and effective weight W' result in normal force (F_n), sliding force (F_s), and rotational moment (M) acting at the fluke centroid. A segment of the anchor chain

is illustrated in Fig. 7 with tension T and normal soil resistance Q per unit length following the convention of Neubecker and Randolph (1995). The x - z coordinate system is as shown in Fig. 7 taking z as downward positive.

The dragging in process causes DEAs and VLAs to dive to reach an ultimate equilibrium state when they translate horizontally without diving further. The final equilibrium depth is termed “ultimate embedment depth,” which essentially determines the ultimate holding capacity. For SEPLAs and indeed other anchors, with careful choice of geometry, anchors can be designed to “dive,” i.e., embed deeper (Tian et al. 2014). The ultimate embedment depth z_c for an anchor model as simplified in Fig. 7 can be approximately evaluated using the below equation:

$$\frac{z_c}{B} = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \quad (1)$$

where:

$$a = (1 + \mu^2) \frac{E_n d N_c}{B}$$

$$b = 2N_t \frac{L}{B} \left[\cos \theta_a + \mu \sin \theta_a - e^{\mu(\theta_a - \theta_m)} (\cos \theta_m + \mu \sin \theta_m) \right] + 2(1 + \mu^2) \frac{E_n d N_c}{B} \left(\frac{s_{um}}{kB} - \sqrt{1 + \eta^2} \frac{e_n}{B} \sin \theta_a \right)$$

$$c = 2N_t \frac{L s_{um}}{B kB} \left[\cos \theta_a + \mu \sin \theta_a - e^{\mu(\theta_a - \theta_m)} (\cos \theta_m + \mu \sin \theta_m) \right] + (1 + \mu^2) \frac{E_n d N_c}{B} \left[(1 + \eta^2) \frac{e_n^2}{B^2} \sin^2 \theta_a - 2 \frac{s_{um}}{kB} \sqrt{1 + \eta^2} \frac{e_n}{B} \sin \theta_a \right]$$

where E_n is the effective width multiplier taking 2.5, d is the diameter of the chain bar, and N_c is a bearing capacity factor for the anchor chain taking ~ 7.5 , μ is the chain friction coefficient taking ~ 0.2 – 0.3 . The undrained shear strength, s_u , can be expressed as $s_{um} + kz$ to describe the increasing soil shear strength with depth for offshore sediments. $N_t = T_a / B L s_u$ is the normalized tension force; θ_a is load angle at padeye, explicitly evaluated as

$$\theta_a = \tan^{-1} \left(\frac{n N_{n \max}^q}{p q N_{s \max}^{n/p}} \frac{N_s^{q-1}}{N_n^{q-1}} \right) - \tan^{-1} \eta \quad (2)$$

where parameters $N_{n \max}$, $N_{s \max}$, and $N_{m \max}$ are uniaxial bearing capacity factors and parameters n , p , and q determine defining the soil resistance (see Tian et al. 2015 for details).

The Significance of Anchor Diving and Estimation of the Ultimate Holding Capacity

From primitive stone anchors to contemporary high-capacity anchors, anchoring systems have evolved over many centuries with the most significant design breakthrough driven by offshore oil and gas industry. Today, anchoring system plays a fundamental role in oil and gas exploitation (as the industry advances into deep waters and thus requires floating platforms) as well as in the burgeoning renewable energy industry, which is developing floating wind turbines and wave energy converters to produce electricity at the scale of 10–100 MW. As previously discussed, anchor holding capacity is essentially determined by the embedded depth and thus encouraging anchor diving into deeper soil and knowing the ultimate state are of significant meaning for offshore anchoring system developments.

Definition

Doppler velocity log (DVL) is a precision instrument, used to measure water current velocities

over a depth range using the Doppler effect of sound waves scattered back from the seabed. The working frequency range of DVLs ranges from 38 kHz to several MHz. It is one of the widely used equipment for underwater vehicles to achieve high-precision navigation.

Scientific Fundamentals

For underwater vehicles, the bottom tracking feature can be used as an important component in the navigation systems. In this case, DVL uses the Doppler shift between the emitted sound wave and the received bottom reflection to measure the relative speed of the vehicle. This kind of instrument has good accuracy, high sensitivity, and can measure longitudinal and lateral speed. Moreover, the velocity of the vehicle is combined with an initial position, compass or gyro heading, and data from the acceleration sensor. The sensor data are combined to estimate the position of the vehicle, typically by using the Kalman filter method. DVL is used to provide navigation information for ships, remotely operated vehicles (ROVs), human occupied vehicles (HOVs), and autonomous underwater vehicles (AUVs).

Overview

With the development of ocean navigation technology, ship velocity was measured using the taffrail log. This consisted of a small propeller that was towed astern, the rate of rotation of which was measured using a counter. In the 1920s, the log uses the Pitot tube and makes a measurement of differential water pressure beneath the ship. In the middle of the twentieth century, the electromagnetic log was developed. In this log, a magnetic field was produced within a streamlined water-tight sensor unit. This field was present in the water, and the motion of the sensor through this field induces a voltage across the sides of the sensor which was proportional to velocity. In the late 1960s and early 1970s, the electromagnetic log had further development.

All the logs so far mentioned made their measurements of velocity relative to the water and not

relative to the seabed. Therefore, their readings were affected by ocean currents. Also, the electromagnetic log and the Pitot tube made measurements within the boundary layer and therefore suffer from further inaccuracies. It was in order to overcome these deficiencies that considerable attention had been given in the following years to the development of next-generation logs, which was the acoustic logs.

The electromagnetic log made using the principle of Faraday's electromagnetic induction made up for the defects of the hydraulic log incapable of measuring the backward speed and low measurement sensitivity. After that, with the development of electronic technology, corresponding improvements were made to the rotary and dynamic pressure log. In the late 1960s and early 1970s, the electromagnetic log had further development.

In the 1970s, Doppler velocity log products using the Doppler effect were successfully developed and quickly applied. In the next few years, the Doppler log had been well developed, and the commercial productions included those made by the companies, such as Amatek, Edo-Western, Krupp, Simrad, Furuno, Magnavox, Thomson CSF, True Digital, and Sperry. These logs had a wide range of operating frequencies, from approximately 100 kHz to 1 MHz. Ideally, they operated in the ground tracking mode in which the frequency of a seabed echo was measured to give an estimate of the velocity relative to the seabed. Unfortunately, the maximum depth of operation was very limited and when this was exceeded, they must transfer to the water tracking mode. In that mode the back scatter from within the water column itself was used, usually from quite short ranges, but still far enough away to be outside the boundary layer. This gave the Doppler velocity log a major advantage over the Pitot tube and the electromagnetic log (Denbigh 1984).

General Principles

Consider a vehicle moving with a forward velocity component v_x and radiating an acoustic pencil beam declined at an angle ϕ relative to this

Doppler Velocity Log for Navigation System in Underwater Vehicle,

Fig. 1 Basic geometry of Doppler velocity log.
(Denbigh 1984)

forward velocity vector, as shown in Fig. 1. The beam strikes the sea bed, and, because the ship has a velocity component $v_x \cos \phi$ in the direction of that region of the seabed, the back-scattered signal has a Doppler frequency shift f_D given by:

$$f_D = \frac{2v_x}{c} f \cos \phi$$

where f is the transmitted frequency of the Doppler velocity log and c is the velocity of the sound in the water.

The principle of the Doppler velocity log is to measure the Doppler shift and to deduce the velocity, knowing the declination angle ϕ . The most appropriate value of ϕ is uncertain due to the finite beamwidth, and a major difficulty with the Doppler log is that of constraining the beamwidth to a sufficiently low value. A typical system would have a 3 dB beamwidth of 5 degrees.

In Doppler velocity log, the problem is aggravated by the considerable back scatter from micro-bubbles and particulate matter in the water, and the use of pulses is essential. A tone burst transmission is used, therefore, and an appropriate portion of the return signal is selected for frequency measurement. From the frequency shift, the forward velocity can be deduced using the given equation of f_D .

A major practical problem is that a vertical ship velocity, or heave, also contributes to the Doppler shift. Moreover, pitching is an additional problem as the beam angle ϕ is then no longer constant. The basic technique for overcoming these two effects is to use two beams: one facing forwards and one facing aft, and to measure the difference frequency. This is known as the Janus system. To a first approximation, the increase in frequency in one beam due to pitch and heave is accompanied by a similar increase in frequency in the other beam, so that subtraction of the two measurements gives a frequency which depends only on the required forward velocity. Small errors still remain, however (Denbigh 1984).

Key Research Findings

As the drift errors of inertial sensors are inevitable, the output of the pure inertial navigation system diverges over time. There are many optional sensors that can be used to suppress the inertial measurement units (IMUs) drift, among them DVL is often used to assist the underwater inertial navigation system (INS). The INS/DVL integrated navigation mainly uses the velocity of DVL to restrain the INS accumulation error. Currently, the integration of INS and DVL has even become

Doppler Velocity Log for Navigation System in Underwater Vehicle, Fig. 2 SINS/DVL integrated navigation structure. (Bao et al. 2020)

a standard configuration for AUV navigation (Bao et al. 2020).

In many applications, the DVL-aided inertial navigation system uses a depth sensor and compass as auxiliary sensors. Figure 2 shows a typical integrated navigation structure for AUV. The system framework contains a strap-down inertial navigation system (SINS), error state Kalman filter, aiding navigation sensors, such as DVL, compass, and pressure sensor. In Fig. 2, the error state Kalman filter is used to estimate the SINS navigation errors. The navigation solution and the navigation error estimates are independent of each other; the navigation error estimates are transmitted to the SINS to reset the navigation parameters. Subsequently, the corrected navigation parameters are used as recent initial conditions of the navigation equations (Jalving et al. 2004; Bao et al. 2020).

In underwater navigation, DVL is commonly installed in the bottom of AUV. The DVL malfunctions in the case of large rolls and pitches of AUV. In addition, the data update rate of DVL is low, and DVL usually works in a specific underwater environment, therefore, the application of DVL is occasionally limited. In many underwater

missions, the SINS/DVL is usually combined with GPS, ultrashort baseline (USBL), or other aiding means to enhance the navigation performance and reliability.

An integrated navigation system combining INS and DVL for an AUV named Urashima is presented, in which the feedback gain provided by the Kalman Filter is applied to the velocity error caused by INS and DVL. When the DVL becomes invalid in the water, the system uses only the INS output; therefore, it is more reliable than a dead reckoning system using the DVL. Furthermore, homing sonar and an acoustic receiver are used as navigation assisting devices to further improve the navigation accuracy (Ishibashi et al. 2004; Aoki et al. 2008). A SINS/DVL navigation system considering range measurement for AUV was proposed. Two measurement models based on acoustic range sensors were derived and augmented to the DVL-assisted SINS, respectively. Simulation results with experimental data demonstrate the improvement of the navigational performance and the robustness of the system to the dropout of acoustic sensor signals (Lee et al. 2004a; Lee et al. 2004b; Lee et al. 2007). Considering sea current estimation, DVL with water-

Doppler Velocity Log for Navigation System in Underwater Vehicle, Fig. 3 Explorer DVL mounted to the VideoRay Pro4. (Snyder 2010)

track is integrated with the INS by providing velocity aiding. Experimental results using real AUV data show that the accuracy and robustness of the integrated navigation system are significantly enhanced (Hegrenæs and Berglund 2009). The integration of IMU, DVL, and USBL is used for the Pirajuba AUV navigation, and the fusion of sample data given by the aforementioned sensors is accomplished through an asynchronous extended Kalman filter (EKF) (Zanoni and de Barros 2015).

DVL is a commonly used aiding source for the INS; however, the DVL must lock the seafloor to measure the AUV velocity, and DVL will fail to work in the mid-water zone or on a very rough seabed owing to the loss of bottom track. In some underwater missions, the SINS/DVL requires additional aiding to perform more precise and reliable navigation. Similar to inertial navigation, the DVL-aided INS is a dead reckoning positioning system. The SINS/DVL integrated navigation only reduces the growth rate of the position error with time for AUV and cannot alter the cumulative characteristics of the position error over time.

Examples of Application

Snyder (2010) has been working with Teledyne-RDI and VideoRay to integrate and test a self-contained, phased-array DVL on the VideoRay

Pro4 mini-ROV, as shown in Fig. 3. The Pro4 has the demonstrated ability to carry the payload of the DVL, combined with the data bandwidth and the power supply to effectively host the navigation system and provide the necessary topside user interface. The integrated system performance in open water on a controlled course and the results of testing this integrated solution in a confined water tunnel are well obtained in the test experiment. Moreover, the application of the solution on a ship hull inspection are demonstrated.

Tal et al. (2017) have extended loosely coupled (ELC) approach for calculating vehicle velocity when only partial DVL measurements are available. This is made possible by using the partial measured raw data from the DVL combined with additional information. In order to examine and demonstrate the improvement of the navigation performance under the ELC approach, Tal et al. develop the TAUV six degrees of freedom (6DOF) simulation, which includes all functional subsystems, as shown in Fig. 4. This simulation consists of the AUV guidance, navigation, and control subsystems and uses a complete hydrodynamic model. Simulation results show great improvement in the navigation performance using the proposed approach compared to the standalone TAUV INS solution.

The Slocum Electric Glider is a buoyancy-driven autonomous underwater vehicle (AUV) capable of long-term deployments typically

Doppler Velocity Log for Navigation System in Underwater Vehicle, Fig. 4 Top level diagram of the TAUV navigation system. (Tal et al. 2017)

Doppler Velocity Log for Navigation System in Underwater Vehicle, Fig. 5 (a) The flight path of a glider deployment from July 22, 2010, to August 3, 2010, off the coast of New Jersey. (b) The vehicle was equipped with a DVL that performed bottom tracking throughout the mission. (Woithe et al. 2011)

lasting 4 to 6 weeks. During mission execution, the vehicle makes use of the global positioning system (GPS) to navigate to its commanded waypoints. GPS, however, can only be used while the vehicle is at the surface. While underwater, the glider uses a simple dead reckoning (DR) algorithm to estimate its location and does not find its true position again until its next periodic surfacing. Since there is limited sensory input to the algorithm, the vehicle's estimated global position can differ significantly from its true position. Woithe et al. (2011) explore the benefits that can be gained if the dead reckoning algorithm makes use of a Doppler velocity log (DVL) to improve a vehicle's location estimates. To gain a quantitative perspective as to how much a DVL may assist in the DR of a glider, Woithe et al. evaluate DVLDR algorithm with a previously flown deployment equipped with a DVL, as shown in Fig. 5. Testing results based on a deployment equipped with the DVL on a Slocum Glider show promising results.

Future Direction of Research

- 1) A small and low-priced DVL targeting micro ROV, UUV and AUV.
- 2) Providing more accurate data for navigation and station keeping.

Definition

Drag anchors, which are evolved from conventional ship anchors, are usually penetrated into seabed by drag vessels to transmit an applied tensile load mainly through the fluke to a load bearing stratum.

Scientific Fundamentals

Types of Drag Anchors

Drag anchor is an important component of mooring system in deep water applications. It mainly consists of a broad fluke (providing main resistance, Fig. 1) and a shank (connecting the fluke to the mooring line, Fig. 2). Traditionally, the angle between them is fixed with a potential adjustment before penetration to the seabed but various in different soils, 50° for clay and 30° for sand, etc. (Randolph and Gourvenec 2011). The capacity of the drag anchor is mobilized primarily by the bearing resistance and side resistance on the anchor fluke and the friction along the embedded portion of mooring lines (Fig. 2), usually it can develop a typical holding capacity of tens of its self-weight by penetrating a depths of several times fluke lengths (Gao et al. 2015). However, this traditional fixed-angle fluke anchor is not designed to take the vertical force and hereby is suitable for catenary moorings rather than the taut or semi-taut line moorings in deep water applications.

To overcome the limitation of the traditional drag anchor, the drag-in plate anchors, also called vertically loaded plate anchors (VLAs), were

Drag Anchors, Fig. 1 Schematic of Vryhof drag embedded anchor (Vryhof Anchors 2015)

Drag Anchors, Fig. 2 Components of DEAs (Thompson et al. 2012)

Drag Anchors, Fig. 3 Examples of VLAs (a) Vryhof Stevmanta (Vryhof Anchors 2015) (b) Dennla MK3 (Kim 2005)

developed to withstand both large horizontal and vertical loads. Figure 3 shows the two commonly used VLAs: Vryhof Stevmanta VLA and Bruce Dennla anchor. It can be seen that the shank of VLA is thinner than that for traditional drag anchor, which makes VLA penetrate deeper into the seabed due to less resistance.

Installation of Drag Anchors

The installation process of the drag anchor can be seen in Figs. 2 and 4. Taking the conventional drag anchor as an example, from the starting point where the anchor shank and the mooring line lying on the seabed horizontally (Fig. 4), the anchor is penetrated into the seabed by the drag

force (Fig. 2) transmitted by the installation line from the vessel (Fig. 4). The installation of the drag anchor finishes once the predetermined installation load is reached.

For the penetration of VLAs, it is quite similar to that for the conventional fixed-fluke drag anchor but with an additional “triggering” or “keying” process at the proof load (e.g., typically 80–100% of the maximum intact mooring line load). By “triggering,” the anchor is rotated such that the mooring line or shank applies a force acting approximately normal to the fluke (Fig. 4). As a result, the anchor acts like a large embedded plate but with a high pull out capacity (Murff and Anderson 2001). It is worthy to note

Drag Anchors, Fig. 4 Sketch of the drag anchor installation (Zhang 2011)

that this “keying” process will cause the embedment loss of the VLAs (Randolph and Gourvenec 2011).

Holding Capacity of Drag Anchors

The holding capacity of a drag anchor depends on the ability to penetrate and reach the target installation depth. The determination of its value at a given depth is relatively straightforward and can follow the design charts based on highly empirical equations in which the ultimate capacity is related to the anchor weight in power form (API 2005; Vryhof Anchors 2015).

$$T_A = a \times \left(\frac{W_a}{C} \right)^b \quad (1)$$

where T_A is the anchor capacity in kips (1 kip = 4.448 kN); a is parameter for capacity in kips; W_a is anchor weight in kips; b is the exponent constant; and C equals to 10 kips.

It should be aware of that the design charts are for ultimate penetration of the anchor. However, anchors are in practice seldom or never installed to their ultimate depth (DNV 2017). Hence, to overcome the limitation of the design charts, further advanced approaches are needed. For the

drag anchor loaded normal to its surface, for example, VLA, which behaves like an embedded plate, the holding capacity could be calculated from the plasticity solution

$$T_a = A_f N_c S_u \quad (2)$$

where T_a (i.e., Q_u in Fig. 5) is the holding capacity of the anchor; A_f is the fluke area; N_c is the bearing capacity factor taken as 12–13 for deep flow around anchor, $3 + \pi$ for shallow anchor, the roughness and the shape of the fluke can affect its value (Merifield et al. 2001); and S_u is the local undrained shear strength at fluke level.

For the conventional fixed-fluke drag anchor in engineering practice, its holding capacity is relatively complex due to a relative complex configuration and orientation, and could not be captured precisely by a simple equation in a form of Eq. 2 but would be determined during the prediction of the trajectory, since the conventional fixed fluke anchor mobilizes the holding capacity equal to the load required for installation.

Prediction in Trajectory of Drag Anchor

The installation and final location, which the holding capacity depends on, is the key to identify the

Drag Anchors, Fig. 5 Shallow and deep anchor behavior (Merifield et al. 2001)

working performance of the drag anchor. Methods for prediction in trajectory of drag anchor can be grouped into three categories: limited equilibrium method, plastic limit methods which include the yield envelope method and upper bound method, and analytical method.

Limit equilibrium method is based on the assumption that when the drag anchor penetrating in and cutting the surrounding soil, the forces on the anchor and anchor line need to fulfill the equilibrium equations (Neubecker and Randolph 1996). In principle, the limit equilibrium method works in the following steps but will slightly change according to different assumptions and force models adopted:

1. From a given starting point (e.g., anchor shank horizontal, embedment zero, initial fluke angle β , advance the anchor through a horizontal increment).

2. Based on the assumption of motion parallel to the previous fluke orientation α , calculate the new anchor depth.
3. Calculate the anchor resistances $T_p = fA_p N_c S_u$ and the anchor capacity T_w if necessary according to different force models and the attached line angle θ_a .

For example, the force model proposed by Neubecker and Randolph (1996) is shown in Fig. 6, in which the fluke anchor θ_w and the form factor f are inherent properties of a drag anchor and the average values are 28° and 1.4, respectively.

4. Establish the moment equilibrium around the padeye and adjust the fluke angle β to fulfill the equilibrium equation
5. Repeat the above steps until the fluke angle $\beta = 0$, that is, the ultimate embedment depth is reached

Drag Anchors,**Fig. 6** Anchor force system for force model (O'Neill et al. 2011)**Drag Anchors,****Fig. 7** Loads and displacements at failure for a simplified drag anchor

Plastic limit analysis method based on yield envelop concept considers a simplified force model of fluke anchor, in which all loads are transferred to the mid-point (reference point) in V-H-M form (Fig. 7) and then carried out the finite element analysis to get a yield/failure envelop with fitted parameters (q, m, n, p):

$$\left(\frac{V}{V_{\max}}\right)^q + \left[\left(\frac{M}{M_{\max}}\right)^m + \left(\frac{H}{H_{\max}}\right)^n\right]^{\frac{1}{p}} - 1 = 0 \quad (3)$$

The method is similar to that of Neubecker and Randolph (1996). The only difference lies in the

application of the yield envelope and associated flow in determining the forces on the fluke and anchor displacements (Wu 2017). By ignoring the influence of shank force on the movement and the elastic displacements, the direction of fluke movement is calculated using the following equations after choosing the incremental distance δh :

$$\frac{\delta v}{\delta h} = \frac{\delta f}{\delta V} / \frac{\delta f}{\delta H}, \quad \frac{\delta \beta}{\delta h/B} = \frac{\delta f}{\delta (M/B)} / \frac{\delta f}{\delta H} \quad (4)$$

where B is the width of the fluke.

Upper bound of plasticity method in the prediction of the trajectory of the drag anchor assumes the anchor will penetrate into the soil volume following the path that the required

installation force T_a is minimum (Kim 2005). For a given position of the anchor, by equating the external work performed by the installation force T_a at the padeye and the anchor weight W to the internal energy dissipation in the soil, the minimum installation force T_a for a given anchor orientation θ_f can be obtained. By changing the anchor orientation and repeating this process, the locus relating minimum anchor line force $T_{a, \min}$ to θ_f is established. Furthermore, the inverse-catenary chain solution also gives a $T_a - \theta_f$ relation. The intersection of the two curves gives the unique values of anchor force T_a and inclination angle θ_f at a given step in the drag embedment process. Steps can be repeated until the fluke is parallel to the seabed. Note that the inverse catenary chain solution can be different according to different soil profiles (Wu 2017).

Analytic method (Liu et al. 2012) considered the installation of the drag anchor as a process in which the anchor penetrates following a circle path with a moving circle center $P_d (x_d, 0)$ (i.e., dragging by a vessel at a constant velocity, V_0) and the changing radius L , as shown in Fig. 8. Hence, the location of the anchor (x, z) needs to fulfill the equations below:

$$(x - x_d)^2 + z^2 = L^2 \quad (5a)$$

$$z = L \sin \theta \quad (5b)$$

Drag Anchors, Fig. 8 The kinematic model of the anchor

$$x_d = L \left\{ 1 + \cos \theta_a \left[\ln \left(\tan \frac{\theta_a}{2} \right) - \ln \left(\tan \frac{\theta_a - \theta}{2} \right) \right] \right\} \quad (5c)$$

in which θ_a is constant for a confirmed shape (Zhang 2011), the radius L and the angle θ can be determined by the reverse catenary chain solution.

The prediction of the trajectory is still challenging for the applications of drag anchors. Different methods could predict the trajectory quite different. The advantages and limitations of the methods are compared in Table 1 (Wu 2017).

Deep-Waters Applications of Drag Anchors

A summary of typical deep-water applications of drag anchors (including conventional fix-fluke drag anchors and VLAs) for both catenary and taut moorings in Oil&Gas industry is shown in Table 2. Most of the field applications are FPSO located offshore Brazil and Gulf of Mexico. Besides, the semi-submersible platform CNOOC 981 in China also adopted the drag anchor when its operating water depth is below 1500 m. Furthermore, since the application in the first floating spar-type floating windmill HYWIND), the drag anchor is gradually widely used in new energy field as the positioning system in offshore wind turbine as well.

Drag Anchors, Table 1 Advantages and limitations of different methods for anchor trajectory prediction (Wu 2017)

Method	Advantages	Limitations
Limit equilibrium method	The earliest method for anchor trajectory prediction based on geotechnical knowledge The method is based on the calculation of soil resistance on all the elements using given equations	Empirical constants which determined from field and laboratory tests are required Parametric study proved that the assumed factors for the resistance calculation influence the accuracy of prediction
Upper bound method	The method is based on the theory of plastic limit analysis, which is more efficient in solving the collapse problem	The application of the method is complex with requirement of comprehensive optimization analyses
Yield envelope method	Finite element analysis can be used for the yield envelopes study The prediction flowchart can be easily applied	The shallow anchor behavior is ignored
Analytical method	The method can be used for arbitrary fluke section in cohesive and noncohesive soil The method is based on a kinematic model and some mathematical expressions	The accuracy of the results from this method depends on the accuracy of the mathematical expressions, which needs to be improved

[Crushing strength of sea ice](#)

Definition

Flexural strength of sea ice is the maximum bending stress that the sea-ice material can take. This definition is drawn from the traditional material mechanics. Once the sea-ice strength is surpassed, the failure and fracture of sea-ice plate are followed. The flexural strength is closely connected with many natural phenomenon and engineering properties of sea ice. For example, the breakup, rafting, and ridge building are often observed in polar area and seasonal ice-covered region, when the ice covers are under the actions of wave, current, and wind. In the cold region, the jacket platform with icebreaking cones, artificial island, slope protection, and icebreaker suffer from the collision of the ice cover. These situations generally cause the bending failure mode of sea ice, and the ice loads of the structures are subsequently determined by the flexural strength.

Uniaxial compression strength is one of the fundamental properties of sea ice. It defines the maximum compressive stress that the ice can bear before failure. The compressive strength is an important engineering property since it involved in most ice-structure interaction scenarios, where ice moves against structures.

Sea-ice ductile-brittle transition is one of the characteristics ice properties under compressive loading when the strain rate raises to a critical level. The effect is important because it marks the point where the compressive strength reaches a maximum and, thus, where the load from a given ice feature against another object approaches its highest value (Schulson and Buck 1995).

Scientific Fundamentals

The Influence of Porosity on the Uniaxial Compression Strength

The uniaxial compressive strength is the most common test for two reasons. First, for the many scenarios where ice moves against vertical structures, the ice load is dominated by the uniaxial strength. The other reason is that the uniaxial compression tests are relatively simple to perform.

The compressive strength of sea ice depends on many factors: the brine volume, air bubble portion, loading direction (relative direction to grain columns), grain size, strain rate, temperature, and ice type (columnar or granular). In this section, we will focus on the influences of porosity, loading direction, and strain rate.

Natural sea ice contains pure ice, brine volume, and air. They have different capabilities to carry compressive forces. In general, the strength depends on the solid material. In another way, the unsolid part can be presented by the total porosity v_t :

$$v_T = v_b + v_a$$

where v_b is brine volume and v_a is air volume. The method to calculate the v_t is explained by Cox and Weeks (1983).

In Fig. 1, it gives the relationship between total porosity fraction and uniaxial compressive strength. It shows that the overall compressive strength has a negative correlation with total porosity. Compared with solid ice, the liquid brine and air are relatively weak for resisting compressive load. The higher porosity means lower solid material to resist the compressive force and thus results in lower compressive strength.

Ductile-Brittle Transition of Sea Ice Under Uniaxial Compression and Its Engineering Applications, Fig. 1 Relationship between total porosity and uniaxial compressive strength under horizontal loading (Timco and Frederking 1990; Moslet 2007)

The Influence of Loading Direction on the Uniaxial Compression Strength

For the unbroken-level ice, the majority part owns columnar structure. The columnar grains make the mechanical properties depend on the angle between loading direction and grains. Due to the anisotropy of the columnar sea ice, the compressive strength may differ significantly when loading horizontally and vertically. The experimental results from different loading direction are given in Fig. 2. It shows that the vertical compressive strength is 4–5 times higher than horizontal compressive strength.

The Influence of Strain Rate on the Uniaxial Compression Strength

Field test on uniaxial compression strength indicated the strain rate or loading speed was one of the dominant factors for the strength value and failure mode. The exact value of strain rate for ductile-brittle transition and the peak value for compression strength might be different because of the variation sea-ice properties (such as microstructure, physical properties, etc.) in different sea area. Figure 3 shows some representative field test results of uniaxial compression strength versus strain rate of sea ice. It shows that the compressive strength increases with strain rate at low strain rate, where the sample fails in ductile manner. At the ductile-to-brittle transition, the strength reaches its maximum value. And the strength decreases with further increasing strain rate. The main mechanism for the different trends depends on the failure procedure as we shall introduce in the following section.

The Other Factors on the Uniaxial Compression Strength

The uniaxial compression strength may also be influenced by other factors such as grain size, environmental history, and ice type. In general, the strength has a positive correlation with the grain size. It is similar to the granular matter,

Ductile-Brittle Transition of Sea Ice Under Uniaxial Compression and Its Engineering Applications, Fig. 2 The influence of loading direction on the uniaxial compressive strength. (a) Results from Timco and Frederking (1990); (b) results from Moslet (2007); (c) results from Ji et al. (2020)

since larger grains are more difficult to be rotated or to slide. The experiment results show that the sea-ice strength from different location may be different even if most of the parameters (porosity, strain rate, loading direction) are similar. It proves that the ice growth history may be important for its mechanical properties. The ice type is also important for the compressive strength. The granular sea

ice is normally considered as an isotropic material. The compressive strength of granular ice is between the vertical and horizontal strength of granular sea ice.

The Ductile-to-Brittle Transition of Sea Ice Under Uniaxial Compression

In section “[The Influence of Strain Rate on the Uniaxial Compression Strength](#),” it shows that the compressive strength is sensitive to strain rate. The correlation between strength and strain rate depends on the material behavior. Sea ice consists of liquid, gas, and solid.

Due to the different strain rates of sea ice under different loading rates, there are three different development trends of cracks in sea ice, and three different models of sea-ice damage are also presented in the macro-perspective (Table 1):

1. When the loading rate is low, the strength of sea ice increases with the increase of the loading rate, and the stress concentration at the crack tip in sea ice is released through creep, which inhibits the crack growth and finally presents a ductile failure mode.
2. When the strain rate is in the ductile-brittle transition, the crack inside the sea ice can grow stably along the principal axis and generate the main crack running through the entire sample, forming split failure, while the sea ice presents a tough-brittle transformation failure.
3. When the loading rate is high, the crack tip of the sea-ice sample cannot grow stably, so the oblique crack is generated and fragmentation is formed, while the sea ice presents a brittle failure mode.

Experimental value of sea-ice ductile-brittle transition could be obtained from the sea-ice compression test under axial action. The simultaneous testing values of axial strain, time history of loading, and indenter displacement were used to reveal the sea-ice behavior of ductile-brittle transition.

How the sea ice would behave during ductile-brittle transition? Let’s take field test on Feb. 6, 2018, in northeast of the Bohai Sea (N 40°07’16’’,

Ductile-Brittle Transition of Sea Ice Under Uniaxial Compression and Its Engineering Applications, Table 1 Physical mechanism for lock-in ice force and steady vibration during ice-structure interaction process

Loading phase	Relatively ice-structure velocity	Physical mechanism		
		Microscale: sea-ice internal micro-cracks	Mesoscale: ice material crushing property of ice	Macroscale: ice edge fracture behavior (contact with structure)
Loading phase	Keep in the same direction, with gradually decreased value	The number of micro-cracks increases as the ice load continues to increase not propagating due to the passivation effect at the crack tips	Under the front part of ductile-brittle transition	Be continuously compressed as complete ice body but not fracture
Loading-unloading transition	Relative rest	Crack saturation and prepare to run through	Under the transition part of ductile-brittle	Prepare to fracture to ice blocks
Unloading phase	Opposite direction	Primary crack run through	Under the latter part of ductile-brittle transition	Fracture to ice blocks which was crowded out by the lateral intact ice sheet

Ductile-Brittle Transition of Sea Ice Under Uniaxial Compression and Its Engineering Applications,

Fig. 4 Micro-crack development and failure mode under various loading/strain speed. Basically from Chen et al. (2018)

In the case test, the strain rate range for ductile-brittle transition 9×10^{-4} – $5 \times 10^{-3} \text{ s}^{-1}$ and the max value for compression strength was almost 6 MPa (Figs. 6–8).

Key Applications

Uniaxial Compressive Strength for Design Load on Vertical Structure

One important application of the uniaxial compressive strength is that it can be used as a

Ductile-Brittle Transition of Sea Ice Under Uniaxial Compression and Its Engineering Applications, Fig. 5 The relationship between failure mode and compressive strength of sea ice. Results from Chen et al. (2018)

The ductile failure processes with multi-racks of sea ice under compression. Results from Chen et al. (2018)

parameter for the calculation of ice action on vertical offshore structures. For the ice floes against vertical structures, the ice is mostly likely to fail by compression between structure and following moving sea ice. The ice load is dominant by the compressive strength. The typical structure encountered sea ice are Molikpaq, Confederation Bridge piers, lighthouses in the Baltic Sea, platforms in the Bohai Sea, and so on.

Three Modes of Ice Load and Structural Responses on Vertical Structure

Field measurement on ice-resistant structure and model test reveals that while the ice speed increases, three modes of ice load and structural responses occur: quasi-static (intermittent) mode, lock-in (steady state) mode, and random (continuous crushing) mode (Kärnä and Turunen 1990; Sodhi 1998; Yue et al. 2009; Guo 2009). ISO19906 recommended shows time histories of ice load and the structure's displacements in three different modes, shown as Fig. 9.

In ISO19906, frequency lock-in (depicted in Fig. 9b) was described as the following: It “can occur at intermediate ice speeds as the time-varying ice actions adapt to the frequency of the

Ductile-Brittle Transition of Sea Ice Under Uniaxial Compression and Its Engineering Applications

Applications, Fig. 7 The splitting failure mechanism of sea ice under compression. Results from Chen et al. (2018)

Applications, Fig. 8 The spalling failure mechanism of sea ice under compression. Results from Chen et al. (2018)

waterline displacements of the structure. The vibrations of the structure are typically sinusoidal in this condition. Similar to intermittent crushing,

the ice-structure interaction exhibits alternating phases of ductile loading and brittle unloading. The time history of the ice action depends on the

Ductile-Brittle Transition of Sea Ice Under Uniaxial Compression and Its Engineering Applications, Fig. 9 Modes of time-varying action due to ice crushing

and the corresponding dynamic component of structural response (ISO19906 2019)

characteristics of the ice and the structure.” During the lock-in ice force and simultaneous similar resonant vibration, the frequency of ice load is locked into the vibrating frequency of structure, which is always the structure’s first natural frequency. So the steady vibration induced by lock-in ice force was also called self-excited vibration.

The ice speed for lock-in ice load is always in a special range. Field measurement on the jacket oil platform with vertical legs in the Bohai Sea shows that the ice speed is lower than 2 m/s for quasi-static (intermittent) mode, 2 ~ 4 cm/s for lock-in (steady state) mode, and higher than 4 m/s for random (continuous crushing) mode (Yue et al.

2009). And the time duration for the steady vibration and lock-in ice force could last from around 20 s to more than 600 s (Qu 2006).

Physical Mechanism for Lock-In Ice Force and Steady Vibration

The understanding of the physical mechanism for frequency lock-in ice force and steady-state vibration on vertical structure was in continuous development. In the 1970s and 1980s, the negative damping model (Blenkarn 1970; Maattanen 1983) was proposed. Later, a more complete

cone in the Bohai Sea. (a) Without cone; (b) after adding cone (Xu et al. 2011)

understanding was proposed, which covers the microscale, development internal micro-cracks of ice; mesoscale, ice crushing properties under different strain rate; and macroscale, ice-structure relative velocity at water level, during acting on vertical ice. This theory was supposed by field measured ice crushing failure process and corresponding ice loads (Sodhi 1998, 2001; Kärnä and Turunen 1990; Yue et al. 2001).

Figure 10 demonstrates the real ice acting process on vertical structures, loading and unloading phase. The ice was moving forward at an almost constant speed (V_{ice}), and the structure was moving as a harmonic motion at an equilibrium position (structure velocity at waterline from $-V_{str} \sim +V_{str}$) (Table 1).

Only if the frequency of each period of loading and unloading phase matched the natural

cone in the Bohai Sea. (a) Before 2004a, without cone; (b) 2004–2005 winter with single cone; (c) 2008–2009 winter with cones on two legs (Xu 2011)

frequency of structure, the repeat phenomenon of micro-cracks deformation in ice and ice force would be stabilized for a while.

Avoiding Ice-Induced Steady Vibration by Adding Cone

Steady-state vibrations were considered to be the most serious problem on ice-resistant vertical structures, which had been ever induced pipeline fracture and flange loosening of some offshore structure. One of the methods to resolve ice-induced steady vibrations was adding icebreaking cones at the water level, thus to change the ice failure mode from crushing to flexural. Several vertical oil jackets were added icebreaking cones to avoid steady vibration and lock-in ice force in the Bohai Sea. And field measurement verified the effect of mitigation of ice-induced vibration and avoidance of steady vibration by adding icebreaking cone (Xu 2011) (Figs. 11 and 12).

Heilongjiang, China

Synonyms

Mooring system; Nonlinear effects; Synthetic lines; The lumped mass method; The rod theory

Introduction

Dynamic analysis method studies the dynamic response of the mooring line under the unsteady external environmental load. Besides, this method is to investigate the design system

stabilization and to identify the stress of the mooring line is within the allowable stress range, which fulfill the mooring system with the specific mooring requirements. Unfortunately, it is difficult to determine, a priori, whether a floating offshore structure-mooring system will experience important dynamic loading. This determination must be made for each design problem on the basis of environmental site conditions, floating offshore structure size, and mooring arrangement.

Scientific Fundamentals

Dynamic analysis method accounts for the time varying effects due to mass, damping, and fluid acceleration. In this approach, the time-varying fairlead motions are calculated from the floating offshore structure's surge, sway, heave, pitch, roll, and yaw motions. Dynamic methods are used to predict mooring line responses to the fairlead motions. Importantly, dynamic methods include the additional loads from the mooring system other than restoring forces, specifically the hydrodynamic damping effects caused by relative motion between the line and fluid. As a simple model established in Fig. 1, following general equation of motion need to be solved.

$$M \frac{\partial^2 x}{\partial t^2} + C \frac{\partial x}{\partial t} + Kx = F$$

where **M**, **C**, and **K** are the matrices of hydrodynamic mass, damping, and stiffness, respectively, and **x** is the displacement vector. **F** represents the total sum of the forces in equation above.

Dynamic Analysis Method, Fig. 1 Simple model of mooring analysis

There are four primary nonlinear effects that can have an important influence on mooring line behavior (API RP 2SK 2005):

(a) **Nonlinear Stretching Behavior of the Line**

The strain or tangential stretch of the line is a function of the tension magnitude. Nonlinear behavior of this type typically occurs only in synthetic materials such as polyester. Chain and wire rope can be regarded as linear. In many cases, the nonlinearity can be ignored and a linearized behavior assumed, using a representative tangent or secant modulus.

(b) **Changes in Geometry**

The geometric nonlinearity is associated with large changes in shape of the mooring line.

(c) **Fluid Loading**

The Morrison equation is most frequently used to represent fluid loading effects on mooring lines. The drag force on the line is proportional to the square of the relative velocity (between the fluid and the line), hence is nonlinear.

(d) **Bottom Effects**

The interaction between the line and the seafloor is usually considered to be a frictional process and is hence nonlinear. In addition, the length of grounded line constantly

changes, causing an interaction between this nonlinearity and the geometric nonlinearity.

The lumped mass method and the slender rod theory are two typical methods to simulate the dynamic characteristics of mooring lines.

The Lumped Mass Method

Van den Boom (1985) describes a technique, which implies that the behavior of a continuous line is modeled as a set of concentrated masses connected by mass-less springs. This involves the lumping of all effects of mass, external forces, and internal reactions at a finite number of points along the line. By applying the equations of dynamic equilibrium (stress/strain) to each mass, a set of discrete equations of motion is derived. These equations may be solved in the time domain using finite difference techniques. Small effects of material damping, bending, and torsion moments are ignored.

Following the paper of Van den Boom (1985), the discretization of the mooring line can be obtained by lumping all forces to a finite number of nodes – so-called “lumped masses” – as given in Fig. 2a. The finite segments connecting the nodes are considered as mass less springs

Dynamic Analysis Method, Fig. 2 Discretization and definitions for lump mass method

accounting for the tangential elasticity of the line. The line is assumed to be fully flexible in bending directions. The hydrodynamic forces are defined in a local system of coordinates (tangential and normal direction) at each mass, as given in Fig. 2b.

In order to derive the equations of motion of the j^{th} lumped mass, Newton's law is written in global coordinates:

$$([M_j] + [m_j(\tau)]) \cdot \ddot{\vec{x}}_j(\tau) = \vec{F}_j(\tau) \quad (1)$$

where $[M_j]$ is the inertia matrix, $[m_j(\tau)]$ is the hydrodynamic inertia matrix, τ is the time, $\vec{x}_j(\tau)$ is the displacement vector, and $\vec{F}_j(\tau)$ is the external force vector.

The hydrodynamic inertia matrix $[m_j(\tau)]$ can be obtained from the normal and tangential fluid forces by directional transformations:

$$[m_j(\tau)] = a_j^n \cdot [\Lambda_j^n(\tau)] + a_j^t \cdot [\Lambda_j^t(\tau)] \quad (2)$$

where a_j^n and a_j^t represent the normal (superscript n) and tangential (superscript t) hydrodynamic mass:

$$a_j^n = \rho \cdot C_M^n \cdot \frac{\pi}{4} \cdot D_j^2 \cdot l_j \quad (3)$$

$$a_j^t = \rho \cdot C_M^t \cdot \frac{\pi}{4} \cdot D_j^2 \cdot l_j \quad (4)$$

In here, C_M^n and C_M^t are the nondimensional normal and tangential hydrodynamic mass coefficients.

$[\Lambda_j^n]$ and $[\Lambda_j^t]$ are directional matrices given below for the two-dimensional case:

$$[\Lambda_j^n] = \begin{pmatrix} +\sin^2 \vec{\phi}_j & -\sin \vec{\phi}_j \cdot \cos \vec{\phi}_j \\ -\sin \vec{\phi}_j \cdot \cos \vec{\phi}_j & +\cos^2 \vec{\phi}_j \end{pmatrix} \quad (5)$$

$$[\Lambda_j^t] = \begin{pmatrix} +\cos^2 \vec{\phi}_j & +\sin \vec{\phi}_j \cdot \cos \vec{\phi}_j \\ +\sin \vec{\phi}_j \cdot \cos \vec{\phi}_j & +\sin^2 \vec{\phi}_j \end{pmatrix} \quad (6)$$

$$\vec{\phi}_j = \frac{\vec{\phi}_j - \vec{\phi}_{j-1}}{2} \quad (7)$$

The nodal force vector, $\vec{F}$, contains contributions from the segment tension, T , the drag force, $\vec{F}_D$, buoyancy and weight, $\vec{F}_W$ and soil forces, $\vec{F}_S$:

$$\begin{aligned} \vec{F}_j(\tau) = & T_j(\tau) \cdot \vec{\Delta x}_j(\tau) - T_{j-1}(\tau) \\ & \cdot \vec{\Delta x}_{j-1}(\tau) + \vec{F}_{D_j}(\tau) + \vec{F}_{W_j}(\tau) \\ & + \vec{F}_{S_j}(\tau) \end{aligned} \quad (8)$$

where $\vec{\Delta x}_j(\tau)$ is the segment basis vector $(\vec{x}_{j-1} - \vec{x})/l_j$, in which l_j is the original segment length.

The drag force, $\vec{F}_D$, may be derived from the normal and tangential force components:

$$\vec{F}_{D_j}(\tau) = [\Omega(\tau)] \cdot \vec{f}_{D_j}(\tau) \quad (9)$$

$$f_{D_j}^n(\tau) = \frac{1}{2} \rho \cdot C_D^n \cdot D_j \cdot l_j \cdot u_j^n(\tau) \cdot |u_j^n(\tau)| \quad (10)$$

$$f_{D_j}^t(\tau) = \frac{1}{2} \rho \cdot C_D^t \cdot D_j \cdot l_j \cdot u_j^t(\tau) \cdot |u_j^t(\tau)| \quad (11)$$

$$\vec{u}_j(\tau) = |T_j(\tau)| \cdot (\vec{c}_j - \vec{x}_j(\tau)) \quad (12)$$

where

$\vec{f}_{D_j}$ = drag force in local coordinates

$\vec{u}_j$ = relative fluid velocity in local coordinates

$\vec{c}_j$ = current vector in global coordinates

ρ = fluid density

D = characteristic segment diameter

l = segment length

C_D = nonlinear (quadratic) 2-D damping (or drag) coefficient

C_D^n = normal drag coefficient

C_D^t = tangential drag coefficient

The directional matrices $[\Omega_j(\tau)]$ and $[T_j(\tau)]$ are used to transform the global drag forces and velocities into local drag forces and velocities:

$$[\Omega_j] = [T_j] = \begin{pmatrix} -\sin \vec{\phi}_j & \cos \vec{\phi}_j \\ \cos \vec{\phi}_j & \sin \vec{\phi}_j \end{pmatrix} \quad (13)$$

C_M is a 2-D nondimensional hydrodynamic mass coefficient. C_D is the 2-D quadratic drag coefficient. The hydrodynamic mass and drag coefficients C_M and C_D as they are used in the so-called Morison equations.

Van den Boom (1985) has derived the fluid reactive force coefficients a^n, a^t, C_D^n , and C_D^t from forced oscillation tests and free hanging tension tests with model chain and wire sections. A volumetric diameter, defined by $d_c = 2\sqrt{\nabla/(\pi l)}$ (with ∇ is segment volume and l is segment length), proved to be an accurate parameter in the dimensionless hydrodynamic coefficients. From the model tests it was concluded that frequency-independent coefficients could be used for normal mooring chains and wires.

Dynamic seabed reaction forces do not affect the behavior of the line and can be modeled as critical damped springs to prevent numerical instabilities. Tangential soil friction forces may be of importance when the line part on the bottom is extremely long and transverse soil reactive forces may be of importance for 3-D problems. Both soil effects are neglected here, thus the vertical force component, F_{s3j} , equals:

$$\begin{aligned} F_{s3j} &= -b_j \cdot \dot{x}_{3j} - c_j \cdot x_{3j} & \text{for } x_{3j} < 0 \\ F_{s3j} &= 0 & \text{for } x_{3j} > 0 \end{aligned} \quad (14)$$

The time domain relations between nodal displacements, velocities, and accelerations are approximated by finite difference methods such as the Houbolt scheme which is described by Bathe and Wilson (1976):

$$\begin{aligned} \vec{x}_j(\tau + \Delta\tau) &= \frac{1}{6\Delta\tau} \cdot \left\{ 11\vec{x}_j(\tau + \Delta\tau) - 18\vec{x}_j(\tau) + 9\vec{x}_j(\tau - \Delta\tau) + 2\vec{x}_j(\tau - 2\Delta\tau) \right\} \\ \vec{\ddot{x}}_j(\tau + \Delta\tau) &= \frac{1}{\Delta\tau^2} \cdot \left\{ 2\vec{x}_j(\tau + \Delta\tau) - 5\vec{x}_j(\tau) + 4\vec{x}_j(\tau - \Delta\tau) - \vec{x}_j(\tau - 2\Delta\tau) \right\} \end{aligned} \quad (15)$$

Or:

$$\begin{aligned} \vec{x}_j(\tau + \Delta\tau) &= \frac{5}{2}\vec{x}_j(\tau) - 2\vec{x}_j(\tau - \Delta\tau) \\ &+ \frac{1}{2}\vec{x}_j(\tau - 2\Delta\tau) \\ &+ \frac{1}{2}\Delta\tau^2 \vec{\ddot{x}}_j(\tau + \Delta\tau) \end{aligned} \quad (16)$$

The segment tension $T_j(\tau + \Delta\tau)$ is derived from the node positions by a Newton-Raphson iteration using the additional equation for the constitutive stress-strain relation:

$$\begin{aligned} \vec{\psi}_j(\tau) &= l_j^2 \\ &\cdot \left\{ \vec{\Delta x}_j(\tau) - \left(1 + \frac{T_j(\tau)}{E_j \cdot A_j} \right)^2 \right\} \end{aligned} \quad (17)$$

$$\begin{aligned} \vec{T}^{k+1}(\tau + \Delta\tau) &= \vec{T}^k(\tau + \Delta\tau) \\ &- [\Delta\psi^k(\tau)]^{-1} \cdot \vec{\psi}^k(\tau) \end{aligned} \quad (18)$$

where $\vec{\psi} = (\psi_1, \dots, \psi_j, \dots, \psi_N)$ is segment length error vector, $\vec{T}^k = (T_1, \dots, T_j, \dots, T_N)$ is tentative segment tension vector at the k^{th} iteration, and $\Delta\psi = \partial\psi/\partial T$ is the length error derivative matrix obtained from (16) to (17).

For each time step, the system of (18) should be solved until acceptable convergence of $T^k(\tau + \Delta\tau)$ is obtained. The initial tentative tension can be taken equal to the tension in the previous step. Each node j is connected to the adjacent nodes $j - 1$ and $j + 1$, hence (18) represents a three-diagonal $(N \times 3)$. The so-called Thomas algorithm may efficiently solve such equations. Van den Boom (1985) claims that – certainly for engineering applications – the Lumped Mass

Method (LMM) does provide efficient and accurate predictions of dynamic line motions and tensions.

The Slender Rod Theory

The slender rod theory is a famous beam model used for static and dynamic analysis of the mooring lines and risers in the ocean engineering. It is developed by Garrett (1982) in the nonstretched configuration and improved by Pauling and Webster (1986) into the small stretched case. The small stretched rod model is widely used to make programs, such as CABLE3D, WINPOST. And Chen et al. (2001) made an improvement on the stretch which is simulated with an inserted spring without bending stiffness. As we all known, there is bending stiffness in the polyester line. Webster et al. (2012) showed an improvement on the large stretch based on the nonstretched rod model with bending stiffness.

The mooring line in the space can be described with the radius vector, $\mathbf{r}(s)$, and arc length, s , in the global coordinate directly, see Fig. 3. The Garrett's rod theory and Paulling and Webster's small stretched rod model are created in the global coordinate. The large stretched rod model will be provided in the same way. In Fig. 3, τ , n , b are the unit tangent vector, the unit normal vector and the unit binomial vector, respectively. Webster et al.

Dynamic Analysis Method, Fig. 3 The coordinates of the rod model

(2012) give the motion equation and the constrained stretch equation for the large stretched rod as:

$$\left. \begin{aligned} &\gamma_{ikm}(s) \tilde{M}_{njm} \ddot{u}_{kj} + \\ &\alpha_{ikm}(s) \frac{B_m}{(1 + \varepsilon_m)^4} u_{kn} + \\ &\frac{\beta_{ikm}(s)}{1 + \varepsilon_m} \tilde{\lambda}_m(t) u_{kn} \end{aligned} \right\} = \mu_{im}(s) q_{mn}(t) + \tilde{f}_{in}^{nbc} \quad (19)$$

$$\frac{1}{2} \beta_{ikm}(s) u_{in} u_{kn} - \frac{1}{2} (1 + \varepsilon_w)^2 \eta_{wm}(s) = 0 \quad (20)$$

where ℓ is the element length in the reference configuration, B is the static bending stiffness of the element in the reference configuration, $\tilde{M}$ is the mass matrix, u is the position and slope of the two nodes of the element, ε is the strain, $\tilde{\lambda}$ is the Lagrangian factor, q is the distributed force, $\tilde{f}_{in}^{nbc}$ is the natural boundary condition, $n = 1..3$ is the index for the directions, $m, w = 1..3$ are the index for the points including the first node, the middle point and the last node in the element, $i, j, k = 1..4$ are the index for the positions and slopes, other coefficients are defined as:

$$\begin{aligned} \alpha_{ikm}(s) &= \int_0^\ell a_i''(s) a_k''(s) p_m(s) ds = \frac{\alpha_{ikm}(\xi)}{\ell^3} \\ \beta_{ikm}(s) &= \int_0^\ell a_i'(s) a_k'(s) p_m(s) ds = \frac{\beta_{ikm}(\xi)}{\ell} \\ \gamma_{ikm}(s) &= \int_0^\ell a_i(s) a_k(s) p_m(s) ds = \ell \gamma_{ikm}(\xi) \\ \mu_{im}(s) &= \int_0^\ell a_i(s) p_m(s) ds = \ell \mu_{im}(\xi) \\ \eta_{wm}(s) &= \int_0^\ell p_w(s) p_m(s) ds = \ell \eta_{wm}(\xi) \end{aligned} \quad (21)$$

The control equations can be solved with the finite element method with the numerical algorithm. In the dynamic case, the Moulton method is chosen as its explicit property and good performance. The first and second order derivative of the unknowns with respect to the time are:

$$\dot{\mathbf{d}} = \left\{ \sum_{n=1}^3 \sum_{k=1}^4 \frac{d(u_{kn}(t))}{dt}, \sum_{m=1}^3 \frac{d(\tilde{\lambda}_m(t))}{dt} \right\}^T \quad (22)$$

$$\ddot{\mathbf{d}} = \left\{ \sum_{n=1}^3 \sum_{k=1}^4 \frac{d^2(u_{kn}(t))}{dt^2}, \sum_{m=1}^3 \frac{d^2(\tilde{\lambda}_m(t))}{dt^2} \right\}^T \quad (23)$$

The control equations can be expressed in the matrix form as:

$$\tilde{\mathbf{M}}\ddot{\mathbf{d}} + \mathbf{C}\dot{\mathbf{d}} + \mathbf{K}_{\text{dynamic}}\mathbf{d} = \mathbf{F}_{\text{dynamic}} \quad (24)$$

in which the control equations are divided into two parts including the motion equations and the stretch constrained equations. Each matrix can be expressed as the addition of the two parts $\tilde{\mathbf{M}} = \tilde{\mathbf{M}}^{[1]} + \tilde{\mathbf{M}}^{[2]}$. For the motion equations, the matrixes are:

$$\tilde{\mathbf{M}}^{[1]} = \begin{bmatrix} \gamma_{ikm}(s)M_{njm}(t) & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \quad (25)$$

$$\mathbf{C}^{[1]} = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \quad (26)$$

$$\mathbf{K}_{\text{dynamic}}^{[1]} = \begin{bmatrix} \alpha_{ikm}(s)B_m & \beta_{ikm}(s)u_{kn}^{(0)} \\ +\beta_{ikm}(s)\tilde{\lambda}_m^{(0)} & \\ \beta_{ikm}(s)u_{in}^{(0)} & -\frac{\eta_{wm}(s)}{E_0A_w^t} \left(1 + \frac{\tilde{\lambda}_w^{(0)}}{E_0A_w^t}\right) \end{bmatrix} \quad (27)$$

$$\begin{aligned} \mathbf{F}_{\text{dynamic}}^{[1]} &= \mathbf{F}_{\text{dynamal}}^{(1)} + \mathbf{F}_{\text{dynall}}^{(0)} \\ &= \begin{bmatrix} \mu_{im}(s)q_{mn}^{\text{dynamic}}(t) + f_{in}^{nbc} \\ \mathbf{0} \end{bmatrix} \\ &- \begin{bmatrix} \alpha_{ikm}(s)B_m u_{kn}^{(0)} + \beta_{ikm}(s)\tilde{\lambda}_m^{(0)} u_{kn}^{(0)} \\ \frac{1}{2}\beta_{ikm}(s)u_{in}^{(0)}u_{kn}^{(0)} - \frac{1}{2}\eta_{wm}(s) \left(1 + \frac{\tilde{\lambda}_w^{(0)}}{E_0A_w^t}\right)^2 \end{bmatrix} \end{aligned} \quad (28)$$

where the upper symbol (0) means the time t_n , the (1) means the time $t_{n+1} = t_n + \Delta t$, Δt is the timestep. $\mathbf{C}$ is the structural damping matrix. In the rod system, there are different types of dampings including damping from fluid, damping from ocean bottom, damping from material, and structural damping. The first two dampings are implemented as the external forces like drag force and friction force. The damping from material is calculated with the visco-elastic construction equation as the creeping and relaxation. The last damping is written as the damping matrix $\mathbf{C}$.

For the constrained equations, the matrixes are:

$$\tilde{\mathbf{M}}^{[2]} = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \quad (29)$$

$$\mathbf{C}^{[2]} = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \quad (30)$$

$$\mathbf{K}_{\text{dynamic}}^{[2]} = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \beta_{ikm}(s)u_{in}^{(0)} & -\frac{\eta_{wm}(s)}{E_0A_w^t} \left(1 + \frac{\tilde{\lambda}_w^{(0)}}{E_0A_w^t}\right) \end{bmatrix} \quad (31)$$

$$\begin{aligned} \mathbf{F}_{\text{dynamic}}^{[2]} &= \mathbf{F}_{\text{dynamal}}^{(1)} + \mathbf{F}_{\text{dynall}}^{(0)} \\ &= \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix} - \begin{bmatrix} \mathbf{0} \\ \frac{1}{2}\beta_{ikm}(s)u_{in}^{(0)}u_{kn}^{(0)} - \frac{1}{2}\eta_{wm}(s) \left(1 + \frac{\tilde{\lambda}_w^{(0)}}{E_0A_w^t}\right)^2 \end{bmatrix} \end{aligned} \quad (32)$$

The Moulton method is applied and finally gets the corresponding iterative equations in the time domain as:

$$\begin{aligned} &\left(\tilde{\mathbf{M}}^{(\frac{1}{2})} + \mathbf{C}^{(\frac{1}{2})} \frac{\Delta t}{2} + \mathbf{K}_{\text{dynamic}}^{(\frac{1}{2})} \frac{\Delta t^2}{4} \right) \ddot{\mathbf{d}} \\ &= \mathbf{F}_{\text{dynamal}}^{(\frac{1}{2})} + \mathbf{F}_{\text{dynall}}^{(0)} - \left(\mathbf{C}^{(\frac{1}{2})} \dot{\mathbf{d}}(t_0) + \mathbf{K}_{\text{dynamic}}^{(\frac{1}{2})} \dot{\mathbf{d}}(t_0) \frac{\Delta t}{2} \right) \end{aligned} \quad (33)$$

in which the upper symbol $(\frac{1}{2})$ means the median time $t_n + \frac{1}{2}\Delta t$.

Dynamics of Flowline/Riser Systems

Definition

Pipeline and riser systems are one of the offshore production equipment that plays a vital role in the

transportation of oil and natural gas from subsea wellhead to topsides of the floating units/vessels. Basically, risers are conductor pipes that connect floaters on the sea surface and the wellheads at the seabed. They experience different sources of dynamic loadings coming from wave, currents, VIV, hydrodynamics, vessel motions, and slugs which cause instabilities and vibrations of the system.

Scientific Fundamentals of Riser Structures

Riser Description and Configurations

There are mainly two kinds of risers which are rigid risers and flexible risers. A hybrid riser is the combination of these two.

Rigid Risers

Steel catenary risers (SCR) and top tensioned risers (TTR) are various forms of rigid riser systems. In practice, the top tensioned risers are deployed in shallow waters, but as design for higher water depth is accounted, a new design practice led to the adoption of SCR as shown in Fig. 1 (Bai and Bai 2005).

TTR is very sensitive to heave motion due to wave and current loads because rotation at the top and bottom connections is limited and requires a heave compensator between the riser top and the floater. However, if the top tension is reduced, it will induce larger bending moment along the riser most especially if the riser is operated in an environment with strong current. If it happens the effective tension becomes negative (i.e., compression), then Euler buckling will occur.

The SCR riser is self-compensated for the heave motion, i.e., the riser is lifted off or lowered on the seabed. The catenary riser is sensitive to environmental loads, i.e., wave and current due to the normally low effective tension in the riser.

Flexible Risers

Flexible risers unlike rigid risers are flexible pipes that offer a robust means of producing oil and natural gas in harsh environments. They are capable of accommodating a wide number of

Dynamic Behavior and Fatigue, Fig. 1 Top tensioned risers and steel catenary risers and their components (Bai and Bai 2005)

Dynamic Behavior and Fatigue, Fig. 2

Description of layers in an unbounded flexible pipe (Mac and Sicsic 2018)

different conditions ranging from shallow and deep waters to horizontal and vertical movements; hence, it is suitable for use with floating facilities. Flexible risers come as a layered structure (Fig. 2) with various materials having different functions.

Each layer of a flexible riser performs the following functions:

- The external sheath prevents ingress of seawater to the annulus.
- The tensile armors provide tensile strength to support axial loads and comprise of two or four layers with opposite laying angles to equilibrate the torsional torque.
- The anti-wear layer prevents friction between armor layers.

- The pressure vault provides internal pressure resistance.
- The pressure sheath contains fluid within the pipe bore and provides the fluid transportation capacity.
- The carcass provides collapse resistance to external pressure.

Designs are made by using a mixture of local and international standards to ensure sufficient margin of safety (API 17B 2014 & 17J 2014).

Flexible risers can be installed in a number of different configurations according to the production requirement and site-specific environmental conditions (Bai and Bai 2005). Static analysis shall be carried out to determine the configurations which are based on:

- Global behavior and geometry
- Structural integrity, rigidity, and continuity
- Cross sectional properties
- Means of support
- Material
- Cost

The six main configurations for flexible risers are shown in Fig. 3.

wave models. In each of the wave simulators, wave-induced water particle velocity and acceleration, surface elevation, and dynamical pressure and pressure gradient of an arbitrary point in space and time are defined mathematically. This will allow the wave simulators to compute the wave kinematics during a time domain dynamic analysis. The 2D regular long-crested waves are useful when studying the effects of extreme waves, while 2D random long-crested waves are used when modeling a complete sea state (Bai and Bai 2005).

Figure 4 shows the parameters that are used when defining a 2D regular long-crested wave propagating in the positive x-direction, where

L : wavelength

H : wave height

d : $Z_s - Z_b$ = still water depth

a : wave amplitude ($H/2$)

T : wave period

g : acceleration due to gravity

t : time

α : phase angle (radians)

x : direction of wave propagation

Wave frequency

$$\omega = \frac{2\pi}{T} \quad (1)$$

Wave number

$$K = \frac{2\pi}{L} \quad (2)$$

Hydrodynamic Loads

Wave Simulator

Wave simulators can be established using 2D regular long-crested and 2D random long-crested

Dynamic Behavior and Fatigue, Fig. 3 Flexible riser configurations (Bai and Bai 2005)

Dynamic Behavior and Fatigue, Fig. 4 Defining parameters for 2D regular waves (Bai and Bai 2005)

Dynamic Behavior and Fatigue, Fig. 5 2D regular long-crested waves (Bai and Bai 2005)

The dispersion relation expresses the relationship between the wave period and wavelength and is given by

$$\frac{\omega^2}{gk} = \tanh(kd) \quad (3)$$

2D Regular Long-Crested Waves

Figure 5 shows the 2D regular long-crested waves which are defined by their wave amplitude and frequency. The following expressions present the wave kinematics:

$$\eta = a \cdot \sin(\omega t - kx + \alpha) \quad (4)$$

Fluid velocity component in the x-direction

$$V_x = \frac{agk}{\omega} \cdot \frac{\cosh(k(d+z))}{\cosh(kd)} \cdot \sin(\omega t - kx + \alpha) \quad (5)$$

Fluid velocity component in the z-direction

$$V_z = \frac{agk}{\omega} \cdot \frac{\sinh(k(d+z))}{\cosh(kd)} \cdot \cos(\omega t - kx + \alpha) \quad (6)$$

Fluid acceleration component in the x-direction

$$a_x = agk \cdot \frac{\cosh(k(d+z))}{\cosh(kd)} \cdot \cos(\omega t - kx + \alpha) \quad (7)$$

Fluid acceleration component in the z-direction

$$a_z = -agk \cdot \frac{\sinh(k(d+z))}{\cosh(kd)} \cdot \sin(\omega t - kx + \alpha) \quad (8)$$

Dynamic pressure

$$P_{dyn} = \rho ag \cdot \frac{\cosh(k(d+z))}{\cosh(kd)} \cdot \sin(\omega t - kx + \alpha) \quad (9)$$

2D Random Long-Crested Waves

The 2D random long-crested wave shown in Fig. 8 is formulated based on the use of a wave spectrum of Fig. 6. Input of significant wave height, peak frequency, etc. (input is dependent on type of wave spectrum) defines the characteristics of the sea state (Bai and Bai 2005). The JONSWAP spectrum can be defined as

$$S(\omega) = a_p g^2 (10)^{-5} \exp\left(-\frac{5}{4} \left(\frac{\omega}{\omega_p}\right)^{-4}\right) \gamma^{a_p} \quad (10)$$

$$a_p = \exp\left(\frac{-(\omega - \omega_p)^2}{2\sigma^2 \omega_p^2}\right) \quad (11)$$

Dynamic Behavior and Fatigue, Fig. 6 Wave spectrum (Bai and Bai 2005)

where

ω : angular frequency

ω_p : angular frequency of spectral peak

g : acceleration due to gravity

a_p : Phillip's constant

σ : spectral width parameter

γ : the JONSWAP peakedness parameter determined from

$$\gamma = \begin{cases} 1, & \gamma < 1 \\ \exp\left(5.75 - 0.367T_{peak}\sqrt{\frac{g}{H_s}}\right), & 1 < \gamma < 5 \\ 5, & \gamma > 5 \end{cases} \quad (12)$$

From the wave spectrum, we can obtain several properties. λ_n denotes the n^{th} (stress) spectral moment defined by

$$\lambda_n = \int_0^\infty \omega^n S_{ss}(\omega) d\omega \quad (13)$$

$H_{1/3}$ is the significant wave height and can be found as

$$H_{1/3} = 4\sqrt{\lambda_0} \quad (14)$$

The characteristics wave period T_w may be estimated as

$$T_w \approx 2\pi\sqrt{\frac{\lambda_0}{\lambda_2}} \quad (15)$$

and the spectral bandwidth parameter ε as

$$\varepsilon = \sqrt{1 - \frac{\lambda_2^2}{\lambda_0 \lambda_4}} \quad (16)$$

By performing an inverse transportation, the wave amplitude (a_i) and frequencies (ω_i) of each wave component are extracted from the wave spectrum. Extraction of amplitudes and frequencies from the wave spectrum is for each wave component done according to

$$a_i = \sqrt{2 \cdot \Delta\omega \cdot S(\omega_i)} \quad (17)$$

where

$$\omega_i = i \cdot \Delta\omega$$

(18)

$\Delta\omega$: the constant difference between successive frequencies.

$$K_i = \frac{(\omega_i)^2}{g}$$

(19)

Furthermore, a random phase angle α_i , uniformly distributed between 0 and 2π , is assigned to each wave component. The wave kinematics is thus represented as a sum of linear components (Fig. 7). If “N” is the number of wave components, the sea state at a particular time and location can be represented by (Fig. 8):

Dynamic Behavior and Fatigue, Fig. 7 Connection between a frequency domain and a time domain representation of long-crested waves (Bai and Bai 2005)

Dynamic Behavior and Fatigue, Fig. 8 2D random long-crested waves (Bai and Bai 2005)

Surface elevation

$$\eta = \sum_{i=1}^N a_i \cdot \sin(\omega_i t - k_i x + \alpha_i) \quad (20)$$

Velocity component in the x-direction

$$v_x = g \cdot \sum_{i=1}^N \frac{a_i k_i}{\omega_i} \cdot \frac{\cosh(k_i(d+z))}{\cosh(k_i d)} \cdot \sin(-\omega_i t - k_i x + \alpha_i) \quad (21)$$

Velocity component in the z-direction

$$v_z = g \cdot \sum_{i=1}^N \frac{a_i k_i}{\omega_i} \cdot \frac{\sinh(k_i(d+z))}{\cosh(k_i d)} \cdot \cos(-\omega_i t - k_i x + \alpha_i) \quad (22)$$

Acceleration component in the x-direction

$$a_x = g \cdot \sum_{i=1}^N a_i k_i \cdot \frac{\cosh(k_i(d+z))}{\cosh(k_i d)} \cdot \cos(\omega_i t - k_i x + \alpha_i) \quad (23)$$

Acceleration component in the z-direction

$$a_z = -g \cdot \sum_{i=1}^N a_i k_i \cdot \frac{\sinh(k_i(d+z))}{\cosh(k_i d)} \cdot \sin(\omega_i t - k_i x + \alpha_i) \quad (24)$$

Dynamical pressure

$$P_{dyn} = \rho g \cdot \sum_{i=1}^N a_i \cdot \frac{\cosh(k_i(d+z))}{\cosh(k_i d)} \cdot \sin(\omega_i t - k_i x + \alpha_i) \quad (25)$$

Hydrodynamic Drag and Inertia Forces

Consider a section of pipeline exposed to a flow, it will experience hydrodynamic forces due to the combined effect of increased flow velocity above the pipe and flow separation from the pipe surface (Bai and Bai 2005). Figure 9 shows the velocity distribution around the pipe. The force vectors are:

Pipeline Exposed to Steady Fluid Flow

Fluid drag is associated with flow velocities due to steady currents superposed by any wave that may be present (Fig. 10). The following expression gives the transverse drag force component per unit length of the pipeline.

$$\text{Transverse drag force, } F_D = \frac{1}{2} \rho C_D D v_n |v_n| \quad (26)$$

where

C_D : transverse drag coefficient

v_n : transverse water particle velocity

ρ : density of seawater

D : total external diameter of pipe

Dynamic Behavior and Fatigue, Fig. 9 Flow field around pipe (Bai and Bai 2005)

Dynamic Behavior and Fatigue, Fig. 10

Fluid drag and inertia forces acting on a pipe section (Bai and Bai 2005)

Pipeline Exposed to Accelerated Fluid Flow

A pipeline exposed to an accelerated fluid experiences a force proportional to the acceleration; this force is called the inertia force (Bai and Bai 2005). The following expression gives the transverse inertia force component per unit length of a pipeline:

$$\text{Transverse inertia force, } F_I = \frac{\pi}{4} \rho D^2 C_M a_n \quad (27)$$

where

C_M : $(C_a + 1)$, transverse inertia coefficient
 a_n : transverse water particle acceleration

Morison Equation

Morison et al. (1950) superimposed the linear inertia force (from potential theory and oscillating flows) and the adapted quadratic drag force (from real flows and constant currents) to get the following resultant force per unit length (Journée 2000):

Wave forces

$$F(t) = F_{inertia}(t) + F_{drag}(t) \quad (28)$$

or:

$$F(t) = \frac{\pi}{4} \rho C_M D^2 \cdot \dot{u}(t) + \frac{1}{2} \rho C_D D \cdot u(t) |u(t)| \quad (29)$$

where the first term is the inertia force and the second term the drag force. It is worthy to note that in Eq. 29, the drag and inertia force components are 90° out of phase with each other when seen as functions of time. This reflects a direct

consequence of the phase shift between velocity and acceleration in an oscillatory motion.

The formula presented in Eqs. 26 and 27 do not take into account that the pipe itself may have a velocity and acceleration. The inline force per unit length of a pipe is determined using the complete Morison's equation (Bai and Bai 2005).

Inline force per unit length of a pipe

$$\begin{aligned} F_{IL}(t) = & \frac{1}{2} \rho C_D \left(U - \frac{\partial y}{\partial t} \right) \left| U - \frac{\partial y}{\partial t} \right| \\ & + C_M \frac{\pi}{4} \rho D^2 \frac{\partial U}{\partial t} - (C_M - 1) \\ & \times \frac{\pi}{4} \rho D^2 \frac{\partial^2 y}{\partial t^2} \end{aligned} \quad (30)$$

where

U : instantaneous (time dependant) flow velocity

y : inline displacement of the pipe

$\delta/\delta t$: differentiation with respect to time

Drag and inertia coefficient parameter dependency

In general, the values of the dimensionless drag (C_D) and inertia (C_M) coefficients can be determined experimentally; however, their dependency is given by

$$C_D = C_D(R_e, KC, \alpha, (e/D), (k/D), (A_Z/D)) \quad (31)$$

$$C_M = C_M(R_e, KC, \alpha, (e/D), (A_Z/D)) \quad (32)$$

The following dimensionless quantities are presented:

Reynolds number

Reynolds number indicates the present flow regime (i.e., laminar or turbulent) and is given as

$$R_e = \frac{UL}{\nu} \quad (33)$$

where

R_e : Reynolds number (—)

U : flow velocity (m/s)

L : characteristic length/diameter (D) for pipelines (m)

ν : kinematic viscosity (m^2/s)

Froude number

The Froude number is associated primarily with free surface effects, while wave forces can be exerted on cylinder elements which are so far below the sea surface that no surface disturbance is generated (Journée 2000).

$$F = \frac{v}{\sqrt{g \cdot D}} \quad (34)$$

where

F : Froude number (—)

g : acceleration of gravity (m/s^2)

D : diameter for pipelines (m)

ν : kinematic viscosity (m^2/s)

Keulegan-Carpenter number (KC)

Keulegan and Carpenter (1958) determined C_D and C_M values for various cylinders in an oscillating flow. They discovered that their data could be plotted reasonably as a function of the dimensionless Keulegan-Carpenter number (Journée 2000). However, Keulegan-Carpenter number gives information on how the flow separation around cylinders will be for ambient oscillatory planar flow ($U = U_M \sin((2\pi/T)t + \varepsilon)$) (Bai and Bai 2005) and is given as

$$KC = \frac{U_M T}{D} \quad (35)$$

where

KC : Keulegan – Carpenter number (—)

U_M : flow velocity amplitude (m/s)

T : oscillating flow period (s)

D : pipe diameter (m)

ε : phase angle (radians)

t : time (s)

$$KC = \pi \cdot \frac{H}{D} = 2\pi \frac{\zeta_a}{D} \text{ (deepwater only)} \quad (36)$$

The current flow ratio may be related to classify the flow regimes:

$$\alpha = \frac{U_c}{U_c + U_w} \quad (37)$$

where

U_c : typical current velocity normal to the pipe

U_w : significant wave velocity normal to pipe given for each sea state ($H_S T_P \theta_W$)

Note that $\alpha = 0$ corresponds to pure oscillatory flow due to waves, while $\alpha = 1$ corresponds to pure (steady) current flow.

Sarpkaya beta

Sarpkaya and Isaacson (1981) conducted several experiments using a U-tube to generate an oscillating flow. They found that the ratio

$$\beta = \frac{D^2}{V \cdot T} \quad (38)$$

was convenient for plotting their data which further procession like that of Iversen's modulus gives (Journée 2000):

$$\beta = \frac{R_e}{KC} \quad (39)$$

Dimensionless roughness

Cylinder roughness is generally made dimensionless by dividing it with diameter (Journée 2000):

Dynamic Behavior and Fatigue, Fig. 11 Typical laboratory measurement results from Sarpkaya (Journée 2000)

$$\frac{\varepsilon}{D} \text{ roughness height } / \text{ cylinder diameter} \tag{40}$$

The Keulegan-Carpenter number has stood as the most realistic and useful primary independent parameter for plotting C_D and C_M . This is sometimes augmented by using Re , β , or $\frac{\varepsilon}{D}$ to label-specific curves, thus introducing additional independent information (Journée 2000).

The results of Sarpkaya’s experiments with smooth cylinders in U-tubes are presented as graphs of the coefficients C_D and C_M as functions of β and KC (Journée 2000). Note that in Fig. 11, the horizontal (KC) axis is

Dynamic Behavior and Fatigue, Table 1 Suggested Morison coefficients (Claus 1992)

KC	$Re < 10^5$		$Re > 10^5$	
	C_D	C_M	C_D	C_M
<10	1.2	2.0	0.6	2.0
≥10	1.2	1.5	0.6	1.5

logarithmic. Respective curves on each graph are labeled with appropriate values of β . Claus (1992), for example, suggested the drag and inertia coefficient values as presented in the following Table 1.

Various design codes or rules also specify (or suggest) appropriate values for C_D and C_M .

Dynamic Behavior and Fatigue, Fig. 12 Suggested drag and inertia coefficient values from DNV (Journée 2000)

Dynamic Behavior and Fatigue, Table 2 Morison coefficients by API and SNAME (Journée 2000)

	Smooth		Rough	
	C_D	C_M	C_D	C_M
API	0.65	1.6	1.05	1.2
SNAME	0.65	2.0	1.0	1.8

Those published by Det Norske Veritas (DNV) 1989 or by the American Petroleum Institute (API) are the most widely accepted; the DNV suggestions for design purposes are shown in Fig. 12. The API and SNAME have the simplest approach as shown in Table 2 (Journée 2000).

Dynamic Behavior and Fatigue, Fig. 13 C_L in shear and shear-free flow for $10^3 < Re < 30 \times 10^4$ (Bai and Bai 2005)

Hydrodynamic Lift Forces

Lift Force Using Constant Lift Coefficients

The lift force per unit length of a pipeline can be computed according to (Bai and Bai 2005)

$$\text{Vertical lift force, } F_L = \frac{1}{2} \rho D C_L v_n^2 \quad (41)$$

where

C_L : lift coefficient for pipe on a surface

v_n : transverse water particle velocity (perpendicular to the direction of the lift force)

ρ : density of seawater

D : total external diameter of pipe

Lift Force Using Variable Lift Coefficients

As can be imagined, the hydrodynamic lift coefficient (C_L) will vary as a function of the gap that might exist between the pipeline and the seabed. It can be seen from Fig. 13 that a significant drop in the lift coefficient is present even for very small ratios of e/D . This is true both for the shear and the shear-free flow (Bai and Bai 2005). The lift coefficients according to Fredsøe and Sumer (1997) are given in Fig. 13.

Dynamic Analysis of Offshore Structures

Basic Formulation of Equations of Motion

Before the motion of an offshore structure can be calculated, an analytical representation (mathematical model) is needed for the structure, together with the loadings and restraints (Wilson and Orgill 1984). Based on the free body sketch, the equations of motion are formulated in a straightforward manner, using either Newton's second law or Lagrange's energy methods.

Single Degree of Freedom Analysis

Consider the surge motion for the spread moored ship shown in Fig. 14. Let the motion of m be restricted to its horizontal displacement coordinate $v = v(t)$ of its mass center at G (Fig. 15). Sway, pitch, heave, and yaw motions are neglected. Figure 15 shows the FBD in the vertical plane which depicts the four types of externally applied loads: self-weight W , which is balanced by its buoyant force equal in magnitude to W ; the equivalent environmental forces $p_1(t)$; the equivalent of mooring line restraint force $q(v)$; and the damping force $f(\dot{v})$.

Let $\sum F_v$ denotes the sum of the four types of external force components on m in line with v and

positive in the positive v direction. In these terms, Newton's second law states:

$$\sum F_v = m\ddot{v} \quad (42)$$

where $\ddot{v}$ is the absolute acceleration of G . This equation is particularly useful in single degree of freedom models involving rigid body translation, in which the flexible supports restraining the motion of m are in line with v . When Eq. 42 is applied in the v direction to the FBD, the resulting equation for surge motion becomes (Wilson and Orgill 1984)

$$m\ddot{v} + f(\dot{v}) + q(v) = p_1(t) \quad (43)$$

Multi-Degree of Freedom Analysis

The general set of equations representing structural motion is defined by the following matrix form:

$$M\ddot{\xi} + C\dot{\xi} + K\xi = p \quad (44)$$

Equation 44 represents a finite set of N ordinary, linear differential equations in N -independent coordinates ($\xi_1, \xi_2, \dots, \xi_b, \dots, \xi_N$), in which the

Dynamic Behavior and Fatigue, Fig. 14 A spread mooring configuration (Wilson and Orgill 1984)

Dynamic Behavior and Fatigue, Fig. 15 Free body sketch for the spread moored ship of Fig. 14 (Wilson and Orgill 1984)

coefficient matrices M , K , and C are constant. When $N = 1$, Eq. 44 reduces to a single degree of freedom structural model. The respective terms of ξ, p, M, K , and C are the coordinate vector, the loading vector, and the mass, stiffness, and damping matrices.

Free, Undamped Motion

The governing equation for free and undamped motion of a structural system, i.e., when $C = p = 0$, is given as

$$M\ddot{\xi} + K\xi = 0 \quad (45)$$

Dynamic Analysis of Beams (Pipes) and Cables

Transverse Vibration of Beams and Cables

The transverse dynamic displacement of the beam (applicable for pipes) or cable model shown in Fig. 16 is deduced from Newton's second law as

$$\frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 v}{\partial x^2} \right) - \frac{\partial}{\partial x} \left(P \frac{\partial v}{\partial x} \right) + \bar{c} \frac{\partial v}{\partial t} + \bar{m} \frac{\partial^2 v}{\partial t^2} = \bar{q}(x, t) \quad (46)$$

This is a general form of the linear Bernoulli-Euler dynamic beam-cable equation where EI , P , and $\bar{m}$ are arbitrary functions of x and the

excitation load $\bar{q}(x, t)$ is arbitrary in both x and t . For submerged beams and cables, a more realistic form of damping than the linear approximation $\bar{c}(\partial v / \partial t)$ in Eq. 46 is velocity squared damping, defined by

$$c' \frac{\partial v}{\partial t} \cdot \left| \frac{\partial v}{\partial t} \right| \quad (47)$$

Here c' is an experimental constant which generally depends on the frequency of oscillation of the structural components. Initial and boundary conditions must be specified for solutions to Eq. 46 to be unique. For a cable ($EI = 0$) and for a beam ($EI > 0$).

The following initial conditions are always required:

$$v(x, 0) \text{ and } \frac{\partial v}{\partial t}(x, 0), \text{ for } 0 \leq x \leq \ell \quad (48)$$

In addition, solutions to cable problems require that the end displacements $v(0, t)$ and $v(\ell, t)$ be specified, and solutions to beam problems require four boundary conditions, two at $x = 0$ and two at $x = \ell$.

Two special cases of Eq. 46 that are of practical importance in offshore structural systems are modeled as follows:

1. For an undamped, flexible cable ($EI = 0$) subjected to a tension load P which is independent of x , Eq. 46 becomes

Dynamic Behavior and Fatigue, Fig. 16 Dynamic model of a line element (Wilson and Orgill 1984)

$$-P \frac{\partial^2 v}{\partial x^2} + \bar{m} \frac{\partial^2 v}{\partial t^2} = \bar{q}(x, t) \quad (49)$$

Here m can vary with the longitudinal dimension, but it is constant for most applications.

2. For an undamped beam of constant stiffness EI , a constant $\bar{m}$, and a tension P which is independent of x , Eq. 46 becomes

$$EI \frac{\partial^4 v}{\partial x^4} - P \frac{\partial^2 v}{\partial x^2} + \bar{m} \frac{\partial^2 v}{\partial t^2} = \bar{q}(x, t) \quad (50)$$

Frequencies and Mode Shapes of Beams and Cables

Frequency parameter is given by

$$\omega = Y \sqrt{\frac{P}{\bar{m}}} \quad (51)$$

where

$$Y = \frac{n\pi}{\ell}, n = 1, 2, \dots \quad (52)$$

$$\omega_n = \frac{n\pi}{\ell} \sqrt{\frac{P}{\bar{m}}}, n = 1, 2, \dots \quad (53)$$

For each characteristic value Y , there is a frequency ω_n and a corresponding mode shape $X = X_n$.

$$X_n = C_n \sin \frac{n\pi x}{\ell}, n = 1, 2, \dots \quad (54)$$

in which the coefficients C_n are arbitrary. For fixed ends of the beam or cable

$$\begin{aligned} v(0, t) = 0 \text{ or } (0) = 0; v(\ell, t) = 0 \text{ or } X(\ell) \\ = 0 \end{aligned} \quad (55)$$

The first two mode shapes are shown in Fig. 17. It is observed that the fundamental frequency ω_n corresponds to the half sine wave and the next highest frequency ω_n corresponds to a full sine wave. This mathematical model predicts that ever-increasing frequencies are possible as n becomes larger and larger (Wilson and Orgill 1984).

Slug-Induced Vibration of Deepwater Riser Structure

Onuoha et al. (2018a) (A & B) studied the stress impact of severe slug on riser base and has successfully modeled the dynamic response of deepwater riser (Fig. 18) induced by severe slug buildup with the following equation system:

$$\begin{aligned} EI \frac{\partial^4 w}{\partial y^4} - T_{eff}(y) \frac{\partial^2 w}{\partial y^2} + \rho_f A_i u_{LS}^2 \frac{\partial^2 w}{\partial y^2} \\ + 2\rho_f u_{LS} A_i \frac{\partial^2 w}{\partial y \partial t} - (A_e P_e(y) - A_i P_i(Z, t)) \frac{\partial^2 w}{\partial y^2} \\ + (\rho_r A_r + \rho_f A_i) \frac{\partial^2 w}{\partial t^2} = 0 \end{aligned} \quad (56)$$

$$T_{eff}(y) = W_a(-y + fL) \quad (57)$$

$$Z(t) = F_b(L, u_{GS}) - \alpha(x - x_i) + u_{LS}t \quad (58)$$

$$z_* = \alpha(x - x_i) \quad (59)$$

$$\begin{aligned} F_b(L, u_{SG}) = \left[-7.71 + 5.8 \left(u_{SG} + \frac{1}{u_{SG}} \right) \right] \\ \times \frac{L(y)}{50} \end{aligned} \quad (60)$$

Dynamic Behavior and Fatigue, Fig. 17 The first two mode shapes for both a fixed end cable and simply supported beam (Wilson and Orgill 1984)

Dynamic Behavior and Fatigue, Fig. 18 A flowline-riser subsea production system in undulated seabed terrain

For $z_* \cong 0$, i.e., when $\alpha(x - x_i)$ is very small

(61)

$$Z(t) = F_b(L, u_{SG}) + u_{LS}t \quad (62)$$

$$P_i(Z, t) = \rho_L g Z(t) \quad (63)$$

Boundary conditions

$$w(y, t)|_{y=0} = 0; \frac{\partial w(y, t)}{\partial y} \bigg|_{y=0} = 0 \quad (64)$$

$$w(y, t)|_{y=L} = 0; \frac{\partial w(y, t)}{\partial y} \bigg|_{y=L} = 0 \quad (65)$$

Initial conditions

$$w(y, t) = A \sin \left(\frac{\pi y}{L} \right) \bigg|_{t=0} \quad (66)$$

$$\frac{\partial w(y, t)}{\partial t} \bigg|_{t=0} = 0 \quad (67)$$

Dynamic Behavior and Fatigue, Fig. 19 Space discretization scheme for the top tensioned riser model

where $(w/OD < 0.05/\pi)$ is the small displacement of the riser, i.e., the amplitude, A (Kuiper et al. 2008). Numerical solutions of the discretized elements of

Fig. 19 give the transverse vibrations of the riser structure as shown in Figs. 20, 21, and 22.

Dynamic Behavior and Fatigue, Fig. 20 Transverse vibration of the mid-node (76.2 m) of the riser for $u_{LS} = 0.095 \text{ m/s}$

Dynamic Behavior and Fatigue, Fig. 21 Transverse vibration of different nodes of the riser for $u_{LS} = 0.095 \text{ m/s}$

Vortex-Induced Vibrations (VIV) of Pipelines

The interaction of the vortices with a circular cylinder is the source of the effect that causes vortex-induced vibration. Vortex shedding from

a smooth, circular cylinder in a steady subsonic flow is a function of Reynolds number. The major Reynolds number regimes of vortex shedding from a smooth circular cylinder summarized by Lienhard (1966) are shown in Fig. 23.

Dynamic Behavior and Fatigue, Fig. 22 Transverse displacement of the riser length at different time for the velocity $u_{LS} = 0.095 \text{ m/s}$

Reynolds Number

Vortex shedding from a smooth, circular cylinder in a steady subsonic flow is a function of Reynolds number. The Reynolds number is based on free stream velocity U and cylinder diameter D

$$R_e = \frac{UD}{\nu} \quad (68)$$

Strouhal Number

Strouhal number (S) is the dimensionless proportionality constant between the predominant frequency of vortex shedding and the free stream velocity divided by the cylinder width.

$$f_s = \frac{SU}{D} \quad (69)$$

As the flow velocity is increased or decreased such that the vortex shedding frequency (f_s) approaches the natural frequency (f_n) of an elastic structure, so that

$$f_n = f_s = \frac{SU}{D}, \text{ or } \frac{U}{f_n D} = \frac{U}{f_s D} = \frac{1}{S} = 5 \quad (70)$$

where f_s is the vortex shedding frequency in units of hertz, U is the free stream flow velocity approaching the cylinder, and D is the cylinder diameter. U and D must have consistent units (Blevins 1994). The Strouhal number of a stationary circular cylinder in a subsonic flow is a function of Reynolds number and to a lesser extent surface roughness and free stream turbulence as shown in Fig. 24.

Harmonic Model for VIV

Because vortex shedding is a sinusoidal process, it is reasonable to model the vortex shedding transverse force imposed on a circular cylinder as harmonic in time at the shedding frequency:

$$F_L = \frac{1}{2} \rho U^2 D C_L \sin(\omega_s t) \quad (71)$$

where

ρ : fluid density (must be in mass units)

U : free stream velocity

D : cylinder diameter

C_L : lift coefficient, dimensionless

Dynamic Behavior and Fatigue, Fig. 23 Regimes of fluid flow across smooth circular cylinders (Lienhard 1966)

Dynamic Behavior and Fatigue, Fig. 24 Strouhal number-Reynolds number relationship for circular cylinders. $S = 0.21(1 - 21/R_e)$ for $40 < R_e < 200$ (Lienhard 1966)

Dynamic Behavior and Fatigue, Fig. 25 Cylinder and coordinate system with rigid cylinder mode shown (Blevins 1994)

D

ω_s : $2\pi f_s$, circular vortex shedding frequency, radians/s, where the vortex shedding frequency f_s is given by Eq. 69

t : time, s

F_L : lift force (force perpendicular to the mean flow) per unit length of cylinder

This force is applied to a spring-mounted, damped, rigid cylinder, shown in Fig. 25. The cylinder is restrained to move perpendicular to the flow. The equation of motion of the cylinder is

$$m\ddot{y} + 2m\xi\omega_y\dot{y} + ky = \frac{1}{2}\rho U^2 D C_L \sin \omega_s t \quad (72)$$

where

y : displacement of the cylinder in the vertical plane from its equilibrium position

m : mass per unit length of the cylinder, including added mass

ξ : structural damping factor

k : spring constant, force/unit displacement

$\omega_y = (k/m)^{1/2} = 2\pi f_y$, circular natural frequency of cylinder

Solutions to this linear equation are found by postulating a sinusoidal steady-state response with amplitude A_y , frequency ω_y , and phase φ (Blevins 1994)

$$y = A_y \sin(\omega_s t + \phi) \quad (73)$$

and substituting this equation into Eq. 72. The result is (Thomson 1988)

$$\frac{y}{D} = \frac{\frac{1}{2}\rho U^2 C_L \sin(\omega_s t + \phi)}{k \sqrt{\left[1 - (\omega_s/\omega_y)^2\right]^2 + (2\xi\omega_s/\omega_y)^2}} \quad (74)$$

where the phase angle is defined by

$$\tan \phi = (2\xi\omega_s\omega_y)/(\omega_s^2 - \omega_y^2) \quad (75)$$

The phase angle shifts by 180 degrees as the cylinder passes through $f_s = f_y$. The response is largest when the shedding frequency approximately equals the cylinder natural frequency, $f_s = f_y$, a condition called resonance (Blevins 1994). Using Eqs. 73 and 74, the resonant vibration amplitude is

$$\left. \frac{A_y}{D} \right|_{f_y=f_s} = \frac{\rho U^2 C_L}{4k\xi} = \frac{C_L}{4\pi S^2 \delta_r} \quad (76)$$

Fatigue and Fracture

Definition

Fatigue is the process of progressive localized permanent structural change occurring in a material subjected to conditions, which produce fluctuating stresses and strains at a point or some points and which may culminate in cracks or complete fracture after a sufficient number of fluctuations (ASTM 1972). Fracture can be

Dynamic Behavior and Fatigue, Fig. 26 Three different crack modes

categorized under three categories of opening, shearing, and tearing modes (Fig. 26), which are termed as the modes I, II, and III, respectively (Yu et al. 2011).

1. Under tensile stress σ perpendicular to the crack plane surface, the crack is opened; this is termed as the opening mode, mode I (a).
2. Under shear stress τ parallel to the crack plane surface and perpendicular to the crack tip, the crack is staggered along the crack plane surface; this is termed as the shearing mode, mode II (b).
3. Under shear stress τ parallel to both the crack plane surface and the crack tip, the crack tears the material; this is termed as the tearing mode, mode III (c).

Mechanism

Fatigue is one of the primary reasons for the failure of structural components. The life of a fatigue crack has two parts, initiation and growth (propagation). Crack initiation is a process that forms cracks on the surface of a material. Fatigue leads to progressive and localized structural

damage when any material experiences cyclic loading. Due to cyclic loading, the material experiences continuous and repeated loads or forces at various points on the material. When such loads are high enough, they lead to crack initiation, growth of cracks, and ultimately a fracture. Crack growth is defined as the widening, lengthening, or increase in the number of cracks on a particular surface. The growth of a crack can be attributed to one or more factors including the application of additional loads, thermal stresses, stress concentrations, and repetitive shrinkage/expansion cycles. Crack growth can significantly reduce the load-carrying capacity of a structure and can occur in a variety of materials including metal, wood, and concrete. It is also known as crack propagation (<https://www.corrosionpedia.com/dictionary>).

Fatigue Assessment

Analysis Based on S-N Curves

Subsea production systems and its components such as pipelines, risers, unsupported free spans, welds, J-lay collars, buckle arrestors, riser

touchdown points, and flex joints should be assessed for fatigue. Potential cyclic loads that can cause fatigue damage include vortex-induced vibrations (VIV), wave-induced hydrodynamic loads, platform movements, and cyclic pressure and thermal expansion loads. The fatigue life of the component is defined as the time it takes to develop a through-wall-thickness crack of the component.

For high cycle fatigue assessment, fatigue strength is to be calculated based on laboratory tests (S-N curves) or fracture mechanics (Bai and Bai 2005). Low cycle fatigue of girth welds may be checked based on $\Delta\epsilon$ -N curves. The S-N curves to be used for fatigue life calculation are defined by the following formula:

$$\log N = \log a - m \cdot \log \Delta\sigma \quad (77)$$

where

N : the allowable stress cycle numbers

a & m : parameters defining the curves which are dependent on the material and structural detail

$\Delta\sigma$: stress range including the effect of stress concentration

For the pipe wall thickness in excess of 22 mm, the S-N curve is to take the following form:

$$\log N = \log a - \frac{m}{4} \cdot \log \frac{t}{22} - m \cdot \log \Delta\sigma \quad (78)$$

where t is the nominal wall thickness of the pipe. The fatigue damage can be computed based on the accumulation law by Palmgren-Miner:

$$D_{fat} = \sum_{i=1}^{M_c} \frac{n_i}{N_i} \leq \eta \quad (79)$$

where

D_{fat} : the accumulated fatigue damage

η : allowable damage ratio, to be taken as 0.1

N_i : the number of cycles to failure at the i th stress range defined by S-N curve

n_i : the number of stress cycles with stress range in block i

Dynamic Ice Loads and Structural Responses

Fengwei Guo
DNVGL, Oslo, Norway

Introduction

Importance of the Subject for Engineering

For the designer of a structure deployed in ice-covered waters, the extreme ice load associated with a return period (typically 100 years) is not the only problem to solve. Observation and measurement on full-scale structures have revealed that ice load is usually time-varying, and in some cases severe structure vibration may arise due to ice loading. The same as other dynamic excitations (e.g., by wave, wind, earthquake), dynamic ice load will lead to different problems than that of extreme ice load, which are illustrated in Fig. 1.

- For a structure itself, if the cyclic frequency of dynamic ice load is close to one of the natural frequencies (typically the first-order natural frequency) of structure, resonance might occur, and structure response is likely to be amplified significantly. On the other

hand, dynamic ice loading will cause fluctuating response (stress). Engineering practice has proved that cyclic stress may cause fatigue damage in long term and a local fatigue crack at local spot might propagate rapidly and lead to collapse of structure.

- For the structures with fixed foundation at seabed (e.g., with pile, gravity), strong vibration may reduce the resistance of soil and cause instability or even overturning of structure.
- Besides the structure directly undertaking dynamic ice loading, strong vibration of superstructure (e.g., topside of offshore platform) may cause other hazards. For example, some type of equipment (e.g., long-span pipeline system) may be very vulnerable to vibration, which shall be considered during the design stage.
- Severe structure vibration may lead to other “nonstructural” problems. For example, vibration may have harmful effect to the crew working onboard offshore platform. According to research, people’s body is vulnerable to a certain range of vibration frequencies, and the relative direction (when the person is standing, sitting, or lying down) of vibration also influences the effect.

Difficulty of the Subject

The difficulty of understanding ice load is mainly due to the complex behavior of natural ice (Sanderson 1988), and it can be very difficult to predict the ice load on a given structure. The dynamic ice load is triggered by “cyclic” failure of ice, which is an even more complex physical

Dynamic Ice Loads and Structural Responses,
Fig. 1 Potential problems caused by dynamic ice load

process. The research on dynamic ice load has been performed for decades, but there are still a number of subjects which have not been well understood yet.

The Scope of the Entry

This entry intends to demonstrate the latest achievement of research and engineering practice on dynamic ice load.

History of Dynamic Ice Load Research

Dynamic ice load was first discovered on steel jacket platforms in Cook Inlet, Alaska (Peyton 1968). The measurement on the platforms shows that structure may vibrate when ice floe pass the structure, indicating that ice load must have significant dynamic feature.

Since then, a number of tests have been done (Fig. 2). From the 1970s to 1980s, full-scale measurements were performed on the light-houses and channel markers in the Baltic Sea, in order to collect data of ice-induced structure vibration (Engelbrektson 1977, 1989). From 1999 to 2001, an extensive measurement campaign was conducted on the lighthouse called “Norströmsgrund” which is located offshore Sweden; the measured data includes ice load time series, structure accelerations, ice parameters, etc. (Jochmann and Schwarz 2001; Kärnä and Qu 2009).

In the Bohai Sea, China, another measurement campaign was conducted from 1999 to 2003. The initial purpose was to monitor the ice-induced structure vibration and then guide the icebreaking

vessel operation to mitigate the vibration. The measurement system was used for several ice seasons, and a large amount of data has been collected (Yue et al. 2001).

In addition to full-scale measurements, many model scale tests have been done to study the dynamic ice load (e.g., Toyama et al. 1983).

ISO 19906 (Arctic offshore structures) collects most of the latest engineering practices on dynamic ice load, and they are demonstrated in sections below.

Dynamic Ice Load on Cylindrical Structures

Most offshore structures have cylindrical legs or vertical surface at waterline. The measured ice load data indicates that dynamic ice load on cylinder structure has different characteristics. Depending on different ice drift velocities, three different ice load “modes” may occur (more detailed description may be found in ISO 19906) (Fig. 3):

Intermittent crushing or quasi-static ice load.

This mode is defined as intermittent crushing in ISO 19906 or quasi-static ice load in some other publications. This mode occurs when ice drift velocity is very slow, so that the period of loading-unloading cycle is much longer than the natural period of structure. Normally this mode may be considered as static load case, unless it occurs so frequent that the fluctuating stress has significant contribution to structure fatigue damage.

Dynamic Ice Loads and Structural Responses, Fig. 2 Different types of structure used to measure dynamic ice load (Bjerkås 2006)

Dynamic Ice Loads and Structural Responses, Fig. 3 Three dynamic ice load modes on cylinder structures (simulated time series, similar with that in ISO 19906)

Frequency lock-in. This mode is defined as “frequency lock-in” in ISO 19906. There have been two theories on the frequency of dynamic ice load: one theory believes that the cyclic failure process of ice sheet has its own characteristic frequency, and if this frequency happens to be close to the natural frequency of structure, resonance will occur (Sodhi 1988). Another theory believes that the frequency of ice load is controlled or “tuned” by the structure’s vibration, so the ice-induced vibration is a self-excited process (Blenkarn 1970; Määttänen 1978).

Even though the theoretical disagreement has not been resolved, ISO 19906 adopts the definition of “frequency lock-in” to describe the process when the dynamic ice load becomes very regular (almost harmonic), and ice load’s dominant frequency is close to natural frequency of structure. Due to dynamic amplification, this phenomenon is most likely to cause severe structure vibration.

Continuous crushing or stochastic ice load. When the ice drift velocity is relatively high, the fluctuating ice load becomes more irregular, and the resulting structure response becomes irregular as well. Normally the vibration magnitude by stochastic ice load is lower than that caused by frequency lock-in, but this mode can be important when contributing to the long-term structure fatigue damage (e.g., Liu et al. 2010).

Dynamic Ice Load on Conical Structure

Compared with cylinder structure, there has been less research work on dynamic ice load on

conical structures. One important data resource of this subject is from the measurement of conical structures in the Bohai Sea, China, where ice load and structure response were recorded for several ice seasons, and dynamic ice load function has been developed based on these data (Qu et al. 2006). ISO 19906 adopts the relevant methods (Fig. 4).

Structure Damage Due to Dynamic Ice Load

Back in the 1960s and 1970s, several structures were reported as damaged by excessive ice loading. Investigation afterwards found out that some of the structure damage incident might be (at least partly) due to dynamic ice load and associated dynamic amplification effect. For example, the winter from 1967 to 1968 was an extremely heavy ice season, and a steel jacket platform in China Bohai Bay was completely damaged by massive ice floe. The subsequent investigation concluded that the jacket structure may have experienced strong vibration before damage (Duan et al. 1994). From the 1960s to 1970s, several lighthouses in the Baltic Sea were damaged by ice (Bergdahl 1972), and investigation in recent years (Lehmann 2010) found that severe ice-induced vibration (especially frequency lock-in phenomenon) and dynamic amplification was perhaps the main reason (Figs. 5 and 6).

Apart from the consequence caused by relatively “short-term” (typically in a few minutes or even seconds) excessive ice-induced

Dynamic Ice Loads and Structural Responses,

Fig. 4 Ice load function for conical structures (IceStruct JIP Guideline 2013)

Dynamic Ice Loads and Structural Responses,

Fig. 5 Jacket platform damaged by ice in the Bohai Sea (Duan et al. 1994)

structure vibration (e.g., frequency lock-in for vertical structure), long-term dynamic ice load may also lead to significant structural damage even though the magnitude is low. Structure dynamics theory and practice have concluded that although the stress magnitude is much lower than the yield limit of metal material, cyclic stress over a long period (typically a few years) may lead to fatigue damage, which is believed as the main contributor to most material failure in engineering structure.

Dynamic ice load will result in fluctuating stress in a structure, so that potentially fatigue damage may accumulate over months and years. So far, by engineering practice there was

no clear evidence of structure failure caused by ice-induced fatigue damage; thus the research work on ice-induced structure fatigue is quite limited, and ISO 19906 only includes discussion according to generic technical approach of fatigue assessment. The research by Dalian University of Technology applied the full-scale data and developed a spectral model to evaluate the ice-induced fatigue for steel jacket platforms in the Bohai Sea (Liu et al. 2010), which may be applicable for similar ice condition and structure type. During the joint industry project “IceStruct,” efforts were made to propose more guidance for designers to assess ice-induced fatigue damage (IceStruct Guideline 2013).

Dynamic Ice Loads and Structural Responses,

Fig. 6 Nygrån lighthouse damaged in Baltic Sea. (From Bergdahl 1972, photo taken by Swedish Board of Shipping and Navigation)

Dynamic Ice Loads and Structural Responses,

Fig. 7 Molikpaq during the incident on 12 May 1986 (Timco et al. 2005)

Foundation Damage Due to Dynamic Ice Load

As demonstrated in Introduction, for a fixed foundation structure (e.g., pile foundation or gravity-based), dynamic ice load and vibration at foundation may reduce the resistance capacity of soil. A famous incident which is often mentioned was Molikpaq caisson deployed in the Beaufort Sea offshore Canada during the 1980s: during the winter in 1986, the Molikpaq caisson experienced

enormous amount of ice loading, and especially on 12 May 1986, a large multi-year ice floe hit Molikpaq and led to excessive ice loading and strong vibration of structure. It was believed that the structure foundation was moved and damaged due to liquefaction of soil beneath the structure.

Unfortunately, not much research work has been done on this subject, but the generic methods for geotechnical engineering are applicable provided the foundation response triggered by ice loading (Fig. 7).

Dynamic Ice Loads and Structural Responses,

Fig. 8 Pipeline broken by strong ice-induced vibration on jacket platform (Yue et al. 2001)

Dynamic Ice Loads and Structural Responses, Fig. 9 Illustration of human body reaction on vibration in different positions (ISO 2631 standard, to be replaced by new version)

Superstructure Damage Due to Dynamic Ice Load

As demonstrated in introduction, dynamic ice load may lead to strong vibration of superstructure. For example, a jacket platform for oil production normally has many types of equipment on the topside, which will be affected by the deck's vibration under dynamic ice loading.

In the winter 1999, a jacket platform in China Bohai Sea was hit by a large ice floe, and strong frequency lock in mode vibration lasted for almost 10 min. The survey afterwards found out that one pipeline was broken by the vibration (Fig. 8), fortunately the damaged pipeline segment was for fire extinguishing purpose and contains no

dangerous gas or liquid. However, the incident indicates that if ice-induced vibration is likely to occur on a structure, the design of equipment/pipeline system, etc. shall consider the effect of vibration, and the mechanism is similar with earthquake design (base vibration).

Crew Health Due to Ice-Induced Vibration

Similar with the effect on superstructure (equipment/pipeline, etc.), strong ice-induced vibration might also have negative effect to the crew working on the offshore installations. From the 1980s to 1990s, several jacket platforms were

installed in China Bohai Sea, but ice-induced vibration was not properly taken into account during the design process.

In the first ice seasons, many crew members reported that it was very uncomfortable during ice-induced vibration process, and the feeling was similar with sea sickness. Furthermore, some crew members even reported that it was difficult to fall in sleep during strong vibration, which might affect their work the next day. To systematically evaluate the human body reaction by ice-induced vibration, extensive study was performed by comparing the measured vibration time series and industry standards (e.g., ISO 2631, Fig. 9).

Definition

Dynamic positioning refers to a system to automatically maintain position and heading of a ship or floating marine structure by using its propellers and thrusters. This allows operations at sea where mooring or anchoring is not feasible due to deep water and congestion on the sea bottom. It is much used in the offshore industry.

Introduction

The main components of typical dynamic positioning (DP) system are introduced briefly for

marine operations. The basic principle and functions of DP system are presented. In the ice-covered area, there may exist a lot of challenges regarding DP operations in ice. The development of DP technology applied to marine operations in the ice-covered sea is presented. Finally, experiences regarding realistic marine operation is collected to give some lessons which are useful to improve marine operability in the ice region.

Dynamic Positioning System

Marine cybernetics is a multidiscipline that combines marine technology, control theory, and industrial information technology to address problems of monitoring and control on marine systems. The core of automatic controls is to deal with how you can get a system to behave the way you like. The objective is to find a technically feasible way to act on a given system so that it adheres, as closely as possible, to some desired behavior. A simplified control loop in concept is shown in Fig. 1.

Marine control system is composed of guidance system, navigation system, and control system. The guidance system generates the desired trajectories (such as position, velocity, and acceleration). Waypoint generator establishes the desired way points. Waypoint management system updates the active waypoint based on current position of the ship. Reference computing algorithms generate a smooth feasible trajectory. The navigation system generates the appropriate feedback signals with assistance of sensors (GPS, radar, inertial measurement units, accelerometers, gyro-compass, etc.). The signal will be processed by quality checking before transforming the

Dynamic Positioning in Ice, Fig. 1 Control loop in concept

measured motion to that of the origin of the relevant reference frame. The control system generates appropriate commands. In the control system, wave filter/observer, controller, and control allocation are necessary. The wave filter (observer) is to fill out high-frequency signals from the measurements. The controller is to generate command based on the difference between the desired position and actual position. Control allocation is used to distribute the command into individual actuator commands.

Based on different operational requirements, there are three control objectives in general. The first one is to control the low-frequency motion including autopilots, dynamic positioning (DP), and POSMOOR. The second is to control the wave-frequency motion (heave, roll, and pitch stabilization). The last one is to control both low-frequency and wave-frequency motion such as DP with roll and pitch stabilization in high seas, course keeping, and roll stabilization.

Dynamic positioning system is used to solve the problem of simultaneous control of three states, namely horizontal positions and heading (surge, sway, and yaw motion). A typical DP architecture is composed of process plant,

measurement system, signal processing, control system, reference model, thrust allocation, and power management system. The process plant is the object to be controlled. The measured signal is processed by filter or observer onboard. The control system gives command to the propulsion system based on certain mathematic algorithm. Reference model generates a feasible way for the object to follow. The general command should be distributed to each thruster with thrust allocation system. The power management system delivers the necessary power with certain limits to the propulsion system.

In most operational conditions, the desired trajectory is represented by slowly varying motion (low-frequency motion) compared to the oscillatory motion induced by the waves (wave-frequency motion). The wave-frequency motion is due to first-order wave-induced loads, while slowly varying motion is mainly due to second-order wave loads, current, and wind. From the control plant sense, the main components of DP system are presented in the Fig. 2. Operator gives a command to the reference model which generates the desired position. The observer is to estimate the actual position based on the measurements from sensors. The controller

Dynamic Positioning in Ice, Fig. 2 Marine control plant DP system

collects both the actual and desired position to calculate the required forces to overcome the disturbance from environment at low-frequency range.

Arctic DP Challenges

Challenges from Sea Ice Loads

One of the main challenges for the DP system is from ice. Ice exists in a lot of features due to complex environment in the Arctic area. The normal sea ice includes level/intact ice, ice ridges, ice floes, rafted ice, and rubble piles. The extreme hard glacial ice includes icebergs, ice islands, and growlers. The ice load due to different ice features are varying significantly. For an icebreaker with normal size operating in ice, it may be subject to ice load less than 2 MN in broken ice (ice floes, rafted ice, and rubble piles) and within 5 MN in level ice, larger than 10 MN in ice ridges and larger than 100 MN in the glacial ice. The broken ice is like melt ice cream. The level ice is like hard ice cream, while the glacial ice is like concrete. Due to the limited thrust of propulsion system, DP operation can only be applied in the broken ice field.

The ice force in the real world is changing rapidly and varying significantly, containing low-frequency, wave-frequency, and high-frequency components. The duration of high peaks may last long which is not expected. Therefore, it is very difficult to design a DP system to cope with ice load completely. At present, there is not any theoretical model which can be applied for DP design. We have to rely on both ice model test and numerical simulation though there are a lot of limitations to them.

Changes in Ice Drift Direction

In most ice covered area, ice management are required to reduce ice load impact on the stationkeeping vessels with assistance of icebreakers. As an effective tool, icebreaker is often used to break large ice sheet into small pieces according to requirements of ship owners. Sometimes it can also be used to tow icebergs away when the icebergs could be observed before arriving at the operation site.

The number of icebreakers needed depends on the in situ ice conditions. In general, the most powerful icebreaker should operate on the upstream which is far from the operation site. It could cut large ice sheet into small ones. The smaller icebreaker should operate near the operation site, which breaks the ice floes into pieces. In order to decrease ice load impact, DP vessel is required to bow into the incoming ice. However, ice drift direction is changing in the ice-covered area due to wind, current, wave, etc. Therefore, ice drifting direction has to be monitored from time to time. The area of ice field to be managed should also be adjusted based on the ice drift.

Difficulty with Conventional DP Control

When a vessel operates in sea ice, the environmental forces are substantially different from conventional open-water. Conventional DP systems are not efficient to be used any more according to Gürtner et al. (2012), Hals and Jenssen (2012), Jenssen et al. (2009), and Kerkeni et al. (2013a).

It is difficult or even impossible for a polar vessel to move sideways due to limited deliverable thrust compared to high transverse ice loads. The thrust command using conventional DP systems could not be well implemented for side motion. The vessels should be orientated always against the drifting ice with the bow or the aft end (Kuehnlein 2009). Moreover, it has to turn with a small attack angle and could not rotate on the spot in ice which is significantly different from that in open waters. In addition, when DP system is used in the ice-covered sea directly, the filter or observer will not give good estimation of vessel status and lag behind dramatically. In order to improve the filter's tracking capability, the filter has to filter out less head/position, but this will bring in more aggressive utilization of thruster (Jenssen et al. 2009).

Arctic DP Control Strategy

As we mentioned, conventional DP has insufficient ability to keep the position of a ship in ice. New control strategies have been proposed. Considering the priority of keeping the vessel heading

toward ice drift direction, Zhou et al. (2013) tried a heading controller combined with a mooring system to keep the position of a polar ship in level ice field. The heading controller was used to keep the vessel align with the drifting ice, while a mooring system was used to provide a reactive force to compensate for the mean drift loads of the environment due to ice. A Kalman filter was also applied to filter out the high-frequency components of measured heading signals. The overall schematic of control strategy is shown in Fig. 3.

Kjerstad et al. (2011) introduced a disturbance rejection design with acceleration feedforward to augment performance of conventional control system. The design could be used for a wide range of applications where disturbances can be suppressed to give a resulting linear system characteristics. The disturbance rejection could offer compensation for environmental forces and model uncertainties based on acceleration measurement. Another control algorithm called automatic icevaning was proposed by Kim et al. (2018). The idea is that DP vessel controls its position in a predefined position while heading up toward the ice drifting direction. DP model tests in ice were carried out to demonstrate the performance of the icevaning control method in the ice tank of Korea Research Institute of Ships and Ocean Engineering.

DP Capability in Ice

The capability plot, often presented as a polar diagram with a number of envelopes, is used to establish the vessel's capability to keep position in a certain environment with a certain combination of thrusters. In basic DP design, the capability assessment of a vessel is often based on static environmental and propulsion forces.

Zhou et al. (2012) simulated heading control of a moored icebreaking tanker under level ice regime where a dynamic ice simulator was developed to consider interaction between ice and hull. For the first time, the method of deriving capability plots of moored and DP vessel in ice based on dynamic ice-hull interaction was proposed in terms of maximum ice thickness that the vessel could resist under different ice drift angles. The result is shown in Fig. 4, where "HC" means the cases with heading controller, while "No HC" means the cases without heading controller. It is easy to find that heading controller is helpful to improve the capability of moored vessel in level ice. Later, Kerkeni et al. (2013b) proposed a method for establishing capability plots in broken ice field. The method is also based on dynamic numerical simulations by considering ice concentration, ice drift velocity, ice drift angle, ice thickness, and so on. Some experimental tests were used to validate the proposed method.

Model Test of DP in Ice

From 2010, the HSVA (Hamburg Ship Model Basin) started to perform a European research and development program named DYPIC (dynamic positioning in ice), which will last 3 years. The project is jointly supported by the national research agencies of Germany, France, and Norway. The aim is to improve the testing capability for dynamic positioning in the ice basin conditions. A toolbox for the numerical prediction of stationkeeping capabilities of a polar ship in ice is desired as the scope of the project (Kerkeni et al. 2014).

Many DP model tests under intact ice conditions were carried out in the HSVA in 2012, where a conceptual model-scale Arctic drillship with dynamic positioning system was tested. The vessel model was equipped with six azimuth thrusters. Three of them are located in the stern and others in the bow region. A scale factor of 1:30 with Froude scaling was applied throughout the model testing campaign. The model ice was manufactured according to the standard method within HSVA. The flexural bending is the main failure mode. Therefore, the bending strength of ice should be made as expected based on experience.

The main goal of DP testing was to ensure the heading, surge, and sway of the vessel model to stay as close as constant desired values, which are preset by operators. Any offsets from original position donates deviations from the target. The

displacements of the model, general command by the DP control system, and the delivered thrust of the actuators were measured and then sent back to the DP controller as feedback. Furthermore, all these measurements were recorded and stored in the data acquisition system for further analysis and processing (Baardson 2012; Jenssen et al. 2012; Van der Werff 2012; Dal Santo and Jochmann 2012; Haase et al. 2012; Haase and Jochmann 2013). The movement of drifting ice was achieved by towing the vessel through the ice field rather than pushing ice toward the ship model. The vessel model navigated with its own power in front of the main carriage. The thrusters were controlled with a model-scale DP system through electric engines by adjusting the RPS and the azimuth angles. When the main carriage moved along the ice tank, the vessel model was towed through the ice. The distance from the main carriage to the vessel and the orientation of the vessel were continuously measured by the qualisys motion tracking system during the tests.

Arctic DP Operations

A system called ice detection, tracking, and forecasting (DTF) is often used to ensure a safe and reliable arctic operation. The function of DTF is to forecast weather, different types of ice, tide, and currents. It could be also applied to collect information related to ice conditions and handle data, which is helpful to find most severe ice condition

for alarm system. Some devices are used in the DTF process, such as satellites, airborne plane and helicopters, unmanned aerial vehicles, sonars, autonomous underwater vehicles (AUV), and radar.

The Aurora Borealis, a dynamically positioned vessel for the European Polar Research Icebreaker Consortium was designed as a combination of a heavy icebreaker, a deep-sea drilling ship, and a multipurpose research vessel (Deter et al. 2009). This multipurpose research vessel is a heavy icebreaker with the highest ice class for worldwide operation. It is powered to continuously break in more than 2.5 m of multi-year ice and enables to manage ridges up to 15 m. The ship shall perform research tasks including scientific drilling year-round in the Arctic and Antarctic without any support vessels. The capacity of performing stationkeeping operations in drifting solid ice of more than 2.0 m thickness during drilling and other research tasks is mandatory requirement. A powerful propulsion system with a capacity up to 108 MW is installed for the various tasks including transit at 16 knots, icebreaking, and stationkeeping in ice. The ice model tests for stationkeeping in drifting solid ice of up to 2.0 m thickness, i.e., icebreaking in a practically stationary mode, were carried out in two ice tanks in Helsinki and Hamburg. Based on the results of the Aurora Borealis icebreaker design effort, it was concluded that stationkeeping operation in solid drift ice is feasible.

Keinonen et al. (2000) reported that station keeping with dynamic positioning systems was employed for drilling and diving operations in heavy ice conditions in the offshore Sakhalin. The water depth is 30 m. As the first ever such operation, the DP operation was supported by two icebreakers: Smit Sakhalin and Magadan. The operation lasted 6 weeks in varying ice conditions including ten tenths of ice cover and ice pressure for a level ice thickness ranging from 0.7 to 1.5 m. The operation was carried out successfully with the total ice down time 22%. The limitations on overall performance were believed to be caused by the limited ability of the icebreakers to manage the ice.

The related drilling operations using dynamic positioning in ice in the Arctic Ocean to recover deeply buried sediments was also reported by Moran et al. (2006). In 2004, a convoy of three icebreakers headed north to begin the Arctic Coring Expedition, IODP Expedition 302. The site water depth ranges from 1100 to 1300 m. Ice floes with thickness of 1–3 m covered 90% of the ocean surface, and ice ridges as high as several meters were encountered where floes converged. The ice drifted at speeds of up to 0.15 m/s and changed direction over short time periods, sometimes within 1 h.

A detailed ice management plan had been made before the operation including radar, helicopter, onboard weather observation, and ice monitoring system for DTF. The drilling vessel, the Vidar Viking, remained at a fixed location. Two icebreakers were used to escort drillship. The Sovetskiy Soyuz icebreaker is nuclear-powered which is believed to be the most powerful icebreaker. It broke against the first oncoming heavy ice floes on the upstream. The Oden is powered with diesel-electric which is the last defense to the drillship Vidar Viking by circling on the upstream of the drifting ice. The three ships coordinated their efforts through a central Fleet Manager, at times on a minute-to-minute basis.

The fleet and ice management teams successfully ensured the smooth drilling operations to recover cores from three sites despite severe ice conditions. The drillship Vidar Viking were able to maintain within a watch circle of 50–75 m for drilling up to 9 days. However, manual positioning rather than automatic control mode was used since automatic control lost its function. There were a lot of ice floes around the hull without open water. The vessel cannot move laterally due to high ice load. The operator had to steer bow into the changing ice drift directions continuously.

Conclusion

So far there is no much experience in arctic DP operating in severe ice conditions. To make Arctic

DP operation safe and effective, a well-prepared ice management system is crucial especially in heavy ice conditions. Provided efficient and effective ice management is available, DP operations should be feasible with a DP control system that is designed and capable of compensating for the quickly changing ice forces. However, this will be at the cost of increased usage of thrusters and thus bring in additional wear and maintenance. Moreover, heading control should be prioritized to the position control in order to reduce ice impact. Therefore, ice drift direction should be monitored from time to time.

Economic Assessment

Zhen Gao
Norwegian University of Science and
Technology, Trondheim, Norway

Definition

Economic assessment for a farm of offshore renewable energy devices refers to estimation of the levelized cost of energy including both capital

expenditures and operation and maintenance expenditures as well as the lifetime electricity generation.

LCOE (Levelized Cost of Energy)

There exist many direct and indirect uses of offshore renewable energy. But, most of the devices developed today, offshore wind turbines, wave energy converters, and ocean and tidal current turbines, are designed to generate electricity for commercial use. Cost of energy (or electricity) is the most important criterion for developing such technologies.

The levelized cost of energy (LCOE) is defined as the average total cost to build and operate a power-generating device over its lifetime divided by the total energy output of the device over that lifetime (Wikipedia 2018). In this section, energy means electricity, and typical lifetime of offshore renewable energy devices is 25 years. Using LCOE, we can compare different technologies of electricity generation on a consistent basis.

Formally, LCOE is given by

$$\begin{aligned} \text{LCOE} &= \frac{\text{sum of costs over lifetime}}{\text{sum of electricity produced over lifetime}} \\ &= \frac{\sum_{t=1}^n \frac{I_t + M_t}{(1+r)^t}}{\sum_{t=1}^n \frac{E_t}{(1+r)^t}} \end{aligned}$$

I_t : capital expenditures (CAPEX) in the year t

M_t : operation and maintenance expenditures (OPEX) in the year t

E_t : electricity energy generated in the year t

r : discount rate

n : expected lifetime

The LCOE refers to the lifetime cost and electricity production, and it has a unit of, for example, Euro per kWh. From the cost point of view, it includes both CAPEX and OPEX. CAPEX refers to the initial costs to acquire and install the physical assets, provision of services, and rental of equipment/means for construction work. For example, for an offshore wind farm, it includes design, fabrication, transport, and installation of wind turbine, foundation, electrical equipment like cables and substation, rent for transport vessels, crane vessels and cable laying vessels, marine service such as geotechnical survey, environmental impact study, and project financing and management. OPEX refers to the cost associated with operation and maintenance of the producing assets. For example, it includes continuous costs for personnel, spare parts, rents, supply vessels, and consuming materials that are used for operation, maintenance, repair, and replacement. CAPEX occurs once at the beginning of the project, while OPEX is continuous when the project is running.

Another important part of the LCOE is the lifetime electricity production in terms of kWh. Estimation of lifetime production of offshore renewable energy devices needs to consider the long-term variation of environmental conditions as well as the availability of the devices. For offshore wind turbines, typically the wind turbine power curve is used to estimate the electricity output, taking into account the probability distribution of mean wind speed. This means offshore wind turbines do not always operate at the rated value of the power output, and they operate at a capacity factor (which is defined as the average generated power divided by the rated power) of 40–60%. When an offshore wind farm is considered, potential wake effect on the power production of the whole wind farm should be properly estimated. The electricity output from a tidal turbine farm can be estimated in a similar way. The lifetime

power output from wave energy converters is more complicated and depends on both wave height and period, as well as their joint distribution.

The LCOE for offshore renewable energy devices strongly depends on the Technology Readiness Level (TRL) for different electricity generation technologies. It should be noted that both wave energy and tidal turbine technologies are in the early stage of development, while offshore wind turbine technology, in particular with bottom-fixed foundations, is relatively mature and has already been commercialized. That means there is a significant uncertainty about the LCOE estimation for wave energy converters and tidal turbines. While, there still exists but less uncertainty for the LCOE estimation of offshore wind farms, although it is not easy to get these values from the developers. On the other hand, offshore wind technology evolves, and the LCOE is continuously decreasing.

As shown in Fig. 1, large-scale tidal turbines have been developed and tested at sea, leading to a TRL of 7, but the array economics needs to be demonstrated (Mofor et al. 2014). As for wave energy, most of the concepts are still in the development phase with a typical TRL of 5, meaning that this technology is partially validated, but not fully demonstrated in relevant environment. Some leading WEC concepts have researched TRL 6 and 7, with demonstrations and prototypes at the sea. But in general, wave energy converters are less mature than tidal turbines.

Current Status and Future Prediction

LCOE is a universally adopted parameter to compare the economics of different electricity generation technologies. According to Magagna and Uihlein (2015), a comparison of the LCOE for alternative renewable energy and conventional energy technologies, including wave energy, tidal energy, onshore wind, offshore wind, solar PV, hydropower, and power plant with coal, is shown in Fig. 2. The solid bars indicate the cost range as per 2015, while the shaded bars indicate the expected future cost reductions in 2050. The LCOE of onshore wind is 7–11 Euro cent per kWh, which is similar to that of small-scale

Economic Assessment, Fig. 1 Technology Readiness Level (TRL) for ocean energy (Mofor et al. 2014)

Economic Assessment, Fig. 2 LCOE (Euro cent per kWh) for alternative renewable and conventional energy technologies (Magagna and Uihlein 2015)

Economic Assessment, Fig. 3 Cost breakdown for typical offshore bottom-fixed wind farms in Europe (MAKE Consulting 2016)

hydropower stations and 50% higher than that of large-scale hydropower plants. The LCOE of offshore wind is 12–18 Euro cent per kWh, which is about twice of the onshore wind today, but potentially can be reduced to the same level by 2050. The LCOE of wave and tidal energy devices today is 50–65 and 35–45 Euro cent per kWh, respectively, which is much higher than other technologies and also shows a larger scatter among the different devices. But there is a big potential for cost reduction if both technologies are commercially developed in large-scale farms.

In order to reduce the LCOE for a certain technology, it will be beneficial to look at in detail the cost breakdown in terms of CAPEX and OPEX. In today's offshore wind farms, OPEX is about 10–20% of the total cost, while CAPEX accounts for 80–90%. Figure 3 shows the CAPEX breakdown for different components and their installation for selected European offshore wind farms (MAKE Consulting 2016). Wind turbine itself (including rotor, nacelle, gearbox, and generator) accounts for 30% and its installation 8%, followed by foundation 13%

and its installation 8%, and then power cable and substation. It should be noted that the total cost for the same technology can be very different from project to project. In particular, water depth and distance from shore play a very important role on the cost of individual projects since the cost of foundations and power cables is very much dependent on these two parameters. Moreover, turbine size is continuously increasing, which reduces the installation cost per MW and will also potentially reduce the maintenance cost per MW. On the other hand, the total installation cost, including wind turbine, foundation, and power cable installation, is about 25%, which is expected to reduce since purpose-built installation vessels are being more used.

Unlike the offshore oil and gas platform which is normally one of its kind, offshore wind turbines need to be developed into farms so that the advantage of mass production should be fully used to reduce the cost. Moreover, good logistics for transport and installation operations and good project and finance management will also contribute to cost reduction. Similarly, purpose-built supply vessels are being developed to provide access to offshore wind turbines at higher sea states for maintenance, repair, and replacement to reduce the downtime and the OPEX (Willow and Valpy 2015). Since 2015, there is a positive general trend of cost reduction for offshore wind turbines due to

the improvement and maturation of the offshore wind technology and project management as well as the introduction of large-scale (6–8 MW) wind turbines. In particular, as shown in Fig. 4, the bidders for several offshore wind farms in Europe in 2016, including Borssele 3 and 4 in the Netherlands, Kriegers Flak, and Vesterhav in Denmark, offered quite low bids, from 72 to 60 Euro/MWh. In 2017, Dong Energy and EnBW won the bids to build first subsidy-free offshore wind farms in the North Sea and the Baltic Sea in Germany, respectively (Offshore Wind Industry 2017). A further cost reduction in offshore wind industry is expected, and the LCOE would reach 40–60 Euro/MWh by 2030.

As mentioned, most of the offshore wind turbines today are based on bottom-fixed foundations, and the LCOE discussed above is purely for bottom-fixed (mainly monopile) wind turbines. Floating wind turbines are still in the early stage of development. In addition to the prototypes in Norway, Portugal, Japan, and the USA, Equinor started to operate the world's first floating wind farms of five 6 MW turbines in Scotland since October 2017 based on their Hywind spar technology. The LCOE for this phase has already been reduced significantly by Equinor as compared to that of their 2.3 MW Hywind Demo which was installed in 2009. They also aims for even lower LCOE at 40–60 Euro/MWh by 2030 for large-

Economic Assessment, Fig. 4 Offshore wind LCOE range and trajectory from 2015 to 2030 (Hundleby and Freeman 2017)

scale wind farm development (MontelNews 2018). If this becomes true, the LCOE for floating wind turbines will be comparable to that for bottom-fixed wind turbines.

Definition

Empirical design is a design method generally characterized by the collection of a large amount of data before much speculation as to their significance, or without much idea of what to expect, and is to be contrasted with more theoretical methods in which the collection of empirical data is guided largely by preliminary theoretical exploration of what to expect. The empirical method is necessary in entering hitherto completely unexplored fields and becomes less purely empirical as the acquired mastery of the

field increases. Successful use of an exclusively empirical method demands a higher degree of intuitive ability in the practitioner (from Access Science @McGraw-Hill).

Scientific Fundamentals

What Is Empirical Method?

The word “empirical” means “based only on observation or experiment.” So “empirical evidence” is evidence that is based on observation. And an “empirical question” is one that can be answered through scientific experimentation.

Empirical method means: based on observation or experiment, not on theory. Also implies, results achieved by the trial and error method (www.answers.com).

Strict empiricists are those who derive their rules of practice entirely from experience, to the exclusion of philosophical theory.

This approach is far more successful with simple problems and in games and is often resorted to when no apparent rule applies. This does not mean that the approach need be careless, for an individual can be methodical in manipulating the variables in an attempt to sort through possibilities that may result in success. Nevertheless, this method is often used by people who have little knowledge in the problem area. The trial-and-error approach has been studied from its natural computational point of view (Bei et al. 2013).

What Is Empirical Design Method?

Empirical design method refers to the design method that the researchers determine the appropriate research method and parameters according to the target requirements, conduct repeated tests and comparisons, and find out the targets that meet the requirements. Then the targets will be tested and compared again, until the researcher finds out the most satisfying targets.

The Process of Empirical Design

Through constant testing and error elimination, the designer can explore the system with black box properties by the method. This method is applied unconsciously in the behavior of animals

and consciously in the behavior of humans. Empirical design method is a learning method purely based on experience. By the response of a test black box due to changing the parameters of the black box system intermittently or continuously, the subjects of the applied empirical design seek a way to reach their goal. The success or failure of the subject’s behavior is evaluated by its degree of approaching to the goal or the process of reaching the intermediate goal. When information approaching the goal is given to the subject, the subject will continue to take successful behavior. When information that deviates from the goal is fed back to the subject, the subject will avoid to take unsuccessful behavior. Through this constant trial and evaluation, the subject can gradually achieve the goal to be pursued.

Because the designer does not know where the satisfactory solution lies, before finding the solution or a more satisfactory solution, they have to make a lot of mistakes. The number of mistakes often depends on the designer’s knowledge level and experience. The so-called innovation is the work of a few talents, which is exactly the experience of trial and error.

This kind of method to solve the problem is more likely to be successful when applied to simple problems or games and is often used when there is no other obvious rule that can be used to solve the problem. Trial and error does not mean that the user must try the method unintentionally. The user can systematically control the variables in order to sort out the solution with the best chance to solve the problem successfully.

The Features of Empirical Design

Empirical design has a number of features:

- Solution-oriented: Makes no attempt to discover why a solution works, merely that it is a solution.
- Problem-specific: Makes no attempt to generalize a solution to other problems.
- Nonoptimal: Generally an attempt to find a solution, not all solutions, and not the best solution.
- Needs little knowledge: Can proceed where there is little or no knowledge of the subject.

It is possible to use empirical design (the trial-and-error method) to find all solutions or the best solution, when a testable finite number of possible solutions exist. To find all solutions, one simply makes a note and continues, rather than ending the process, when a solution is found, until all solutions have been tried. To find the best solution, one finds all solutions by the method just described and then comparatively evaluates them based upon some predefined set of criteria, the existence of which is a condition for the possibility of finding a best solution. (Also, when only one solution can exist, as in assembling a jigsaw puzzle, then any solution found is the only solution and so is necessarily the best.)

The Application Example of Empirical Design

Empirical design methods are widely used in various industries, especially in traditional industries such as Navy Architecture and Ocean Engineering, Machinery Manufacturing, etc. In the process of ship design, empirical design methods are needed in many cases, such as in the calculation of hull friction resistance, in the concept design of new ship according to the previous design experience, and so on.

The Calculation of Hull Friction Resistance

Based on the previous calculation experience of hull friction resistance, the researchers have summarized the formula of hull friction resistance coefficient as shown below.

The Schoenheer Formula

In 1932, Schoenheer applied the law of logarithmic velocity distribution and gave the following empirical formula according to the results of the plate drag test.

$$\frac{0.242}{\sqrt{C_f}} = \lg(ReC_f)$$

This is the Schoenheer formula, which is most commonly used in the USA. In 1947, the American Ship Model Test Tank Conference

decided to use this formula as the standard formula to calculate the ship friction resistance, so this formula is also known as the formula 1947 ATTC. Because the formula is very difficult in the actual calculation, therefore, when Re within 10^6 – 10^9 , the formula can be turned into simple formula with the same results.

$$C_f = \frac{0.4631}{(\lg Re)^{2.6}}$$

The Prandtl–Schlichting Formula

By applying the same principle above, Prandtl and Schlichting have obtained the Prandtl–Schlichting formula which is very similar to the Schoenheer formula.

$$C_f = \frac{0.455}{(\lg Re)^{2.58}}$$

This formula is most commonly used in continental Europe and has been widely used in China in the past.

The Hughes Formula

Because the above Schoenheer formula and the Prandtl–Schlichting formula were obtained based on the results of the plate test, geometric similarity was not considered in the analysis. According to the Reynolds theorem in the similarity theory, the theorem that the coefficient of friction resistance is a function of Reynolds number is only applicable to the geometrically similar plates. If the geometric shape of the plate is not similar, that is, the aspect ratio (that is, the width and length ratio) is not equal, then the coefficient of friction resistance should be a function of both Reynolds number and B/L , that is to say,

$$C_f = f\left(Re, \frac{B}{L}\right)$$

The influence of different aspect ratio on the coefficient of friction resistance is called the edge effect.

In 1952, Hughes analyzed a number of previously published plate data and confirmed that the coefficient of friction resistance was related to

the aspect ratio. In 1954, Hughes published his plate test data. In his test, the Reynolds number is between 2×10^4 and 3×10^9 and aspect ratio is between 0.0156 and 42. The formula for a smooth flat plane with an infinite aspect ratio is obtained.

$$C_f = \frac{0.066}{(\lg Re - 2.03)^2}$$

This formula is called the Hughes formula. The calculation result of this formula is smaller than that of the Schoenheer formula, because the Schoenheer formula is derived from the interpolation of the finite aspect ratio (three-dimensional flow) plate data.

The Formula of 1957 ITTC

Although the calculated results according to the existing formulas of smooth plate's friction resistance are very close, there are some differences. In particular, when the ship model test results are converted to the real ship, the calculated resistance of the real ship varies with different formulas. Based on the analysis of the resistance test results of geometrically similar ship model, the Eighth International Ship Model Test Tank Conference (ITTC for short) held in Madrid, Spain, in 1957, believed that the value obtained by the Schoenheer formula at low Reynolds number was low. Finally, the following new formula was proposed. It is called "1957 international model test tank real ship - model conversion formula," abbreviated as "the formula of 1957 ITTC."

$$C_f = \frac{0.075}{(\lg Re - 2)^2}$$

It should be pointed out that the formula of 1957 ITTC is not exactly the formula for calculating the friction resistance coefficient of turbulent smooth plate, and it is used for the resistance conversion between ship model and real ship. China now uses the formula of 1957 ITTC.

According to the empirical calculation method of ship resistance, the frictional resistance coefficient curves calculated by different formulas can be obtained. It can be seen from the curves that, at a low Reynolds number, the slope of the formula

of 1957 ITTC is steeper than other formula's slope, and at high Reynolds number, the result of the formula of 1957 ITTC is not different from the Schoenheer formula's result. Besides, the formula of 1957 ITTC is very similar to the Hughes formula in form, but it is about 12.5% larger in numerical terms than the Hughes formula. While the Prandtl-Schlichting formula is very similar to the Schoenheer formula in form, and it is about 2.0–2.5% larger in numerical terms than the Schoenheer formula at most.

The Concept Design of New Ship

In addition, in order to reduce the wave resistance of ships, designers can adopt different design concepts to design new ships according to the previous design experience. Successful empirical design will lead to the emergence of a new type of ship, which will greatly improve the performance of a ship. Here are some typical empirical design concepts.

Catamaran and Multihull Ship Design Concept

Based on past design experience, researchers have found that catamarans have some unique properties. The catamaran has two pieces, and the friction resistance is larger than that of monohull ship of the same length and displacement. At the same time, the wave interference between two bodies will increase the resistance. However, the length drainage volume coefficient or length-width ratio of each piece of the catamaran is much larger than that of monohull ship, so the wave-making resistance can be significantly reduced. Therefore, in a certain range of speed, the total hull resistance of the catamaran is usually smaller than that of the monohull ship.

Multibody ships, such as three-body ships, not only increase the fineness coefficient or length-width ratio, which can make the wave-making resistance coefficient drop, but also can use the favorable interference between the before-and-aft bodies to further reduce the wave-making resistance.

The Design Concept of Lifting the Hull Out of the Water

Based on previous design experience, the researchers found that it is an effective measure to

reduce wave resistance to slide the hull above the water surface or to leave the water surface. Based on these experiences, the researchers designed planing boat, hydrofoil boat, hovercraft, and so on.

When the planing boat glides in the water, the bottom of the planing boat generates the dynamic lift force to lift most of the boat out of the water, and the drainage volume decreases so as to reduce the wave resistance.

When the hydrofoil boat is in the airfoil condition, the lift force generated by the hydrofoil causes the boat body to be lifted out of the water. Thus, only the hydrofoil and appendage generate resistance in the water. This resistance is relatively small, so the hydrofoil can reach a higher speed.

The hovercraft is a kind of boat that the rising pressure of the air cushion lifts the hull out of the water. The wave-making resistance of the hovercraft decreases as only the apron or side wall appendages produce resistance

The Design Concept of Hull Submergence

It is known from previous design experience and wave theory that the wave-making mainly occurs near free surface, and the wave-making amplitude will decrease exponentially with the increase of immersion depth. Therefore, the design concept of hull submergence is to move part or all of the displacement volume of the hull below the water surface, so as to reduce wave resistance. Based on their design experience, the researchers designed semi-submersibles and diving boats.

Selection and Design of Submarine Structure Materials

There are many kinds of materials on the submersible, which can be divided into pressure-resistant

structure materials and nonpressure-resistant structure materials. Generally, for the selection of pressure-resistant structure materials, the following methods should be followed.

Firstly, according to the function requirements of material design (usage requirements, shape requirements, pressure depth, etc.), design personnel usually select the suitable raw materials, determine the appropriate material processing methods and the process parameters, conduct repeated tests and comparisons, and find out the applicable material whose basic performance meets the requirements. Then the material will be tested and compared again, until the designers find out the most satisfying material. The process is a kind of typical experience design method.

Secondly, the trial-and-error method refers to the method that the designers put forward the working principle of new product according to the existing product or previous design experience and then make sample part through continuous modification and improvement. If the sample part does not meet the requirements, the designer will return to the plan design and start again. Until the sample design is proved to meet the requirements, the sample part can be manufactured in small batches and in batches. As shown in the following Fig. 1, the designers look for solutions along direction A according to experience or existing products. If there is no appropriate solution, they will adjust the direction and search along direction B. If still not, transfer direction to C, D, and so on. The designers did not complete the task until a satisfactory “solution” is encountered in one direction. This is the most primitive way of seeking new things and the first method of technological creation in history.

Introduction

The global warming is caused by greenhouse gases which are accumulating solar heat in the atmosphere by keeping the long wave radiation energy from the earth effectively. Since the latter half of the twentieth century, global warming is concerned by the whole world gradually. In 1992, the United Nations Framework Convention on Climate Change (UNFCCC) which was developed by the United Nations Climate Change Committee was endorsed by 154 countries in the United Nations Conference on Environment and Development in Rio de Janeiro, and came into force on March 21, 1994; this is the first international convention that withstands the global warming by controlling the emission of greenhouse gases overall. Meanwhile, in Tokyo, 1997, for the purpose of

propelling the emission of greenhouse gases, the Kyoto Protocol, which forced the emission of greenhouse gases in developed countries and set standards of emission, was adopted in the Third Conference of the Contracting Governments on Climate Framework Convention and came into force in February 2005. In the same year, the Solution for CO₂ Emission of Ships was adopted by the Contracting Governments based on the International Convention for the Prevention of Pollution from Ships 1973 (MARPOL73/78 Convention), and the Marine Environment Protection Committee (MEPC) was authorized to consider the workable reduction strategies of greenhouse gases.

The Considering Procedure of MEPC for EEDI

The considerations of MEPC for energy efficiency design index (EEDI) are summarized as three stages.

The Stage of Extensive Discussion and Argument, MEPC56–MEPC59

In July 2007, the draft resolution of setting the assessment panel of ship emission reduction was adopted at 56th session of MEPC, since then, the panel including 23 members was to carry out the research of ship emission reduction.

In March 2008, the issues of mandatory CO₂ design index of new ships, guidelines for voluntary and temporary trial of greenhouse gases emission index, and levying marine fuel oil tax worldwide, etc., were discussed at 57th session of MEPC. At the ship owner's request, the mandatory CO₂ Design Index of New Ships was decided to be developed to consider design standards and operational measures and market-based measures separately. During the session, a working group meeting on CO₂ Emission Index Mechanism was added, and the amendments to MARPOL Annex VI of the regulations on harmful gas reduction for ships were adopted.

In October 2008, a Draft of Interim Guidelines on the Method of Calculation of EEDI for New Ships was developed at 58th session of MEPC by changing CO₂ Design Index of New Ships into

EEDI, in consideration of that International Maritime Organization (IMO) were to put forward the standards of new ship design and construction from the point of improving energy efficiency level, other than emphasizing the requirement of greenhouse gases (GHG) reduction.

In March 2009, the EEDI calculation methods were adjusted at the second working group meeting during session.

In July 2009, the Interim Guidelines on the Method of Calculation of EEDI for New Ships were further modified at 59th session of MEPC, and the Interim Guidelines on the Method of Calculation of EEDI and the Interim Guidelines on Voluntary Verification of EEDI were published by Circulars. The guidelines, which were used voluntarily at that stage, encouraged ship owners and designers to design and construct ship with higher energy efficiency standards by technical innovation and energy-saving technology.

The Stage of Development of Operation Measures and Technical Measures

The Regulations on Energy Efficiency for Ships were adopted and added in MARPOL Annex VI at 60–62nd session of MEPC.

In December 2009, the Draft of Amendments for MARPOL Annex VI in which the EEDI was added at some countries' request was developed at 60th session of MEPC; meanwhile a further research on confirmation of base line based on the existing ship data was agreed.

In September 2010, the issue of GHG emission reduction was discussed at 61st session of MEPC; no agreement on how to enforce the energy efficiency management of ships as a part of MARPOL more reasonably was reached. The enforcement of EEDI was delayed.

In July 2011, the EEDI and the Ship Energy Efficiency Management Plan (SEEMP), as the lasting of MARPOL Annex VI, were adopted at 62nd session of MEPC, and came into force on January 1, 2013. In this session, EEDI calculation guidelines, survey and certification guidelines, SEEMP development guidelines, and interim guidelines for minimum installed power and ship speed in adverse conditions were completed. As a result, shipping industry became the first industry

that implemented the CO₂ emission reduction measures worldwide.

The Stage of Measures' Discussion and Preparation of Market Emission Reduction Mechanism

During the stage of issuance and implementation of energy efficiency rules since the 63rd session of MEPC, the implementation problems are being modified and improved.

In February 2012, a series of significant guidelines of enforcing energy efficiency rules were discussed and adopted at 63rd session of MEPC, included:

- Guidelines on the Method of Calculation of the Attained Energy Efficiency Design Index (Attained EEDI) for New Ships
- Guidelines for the Development of a Ship Energy Efficiency Management Plan (SEEMP)
- Guidelines on Survey and Certification of the Energy Efficiency Design Index (EEDI)
- Guidelines for Calculation of Reference Lines for Use with the Energy Efficiency Design Index (EEDI)

In October 2012, the relevant technologies and operation standards on energy efficiency management were developed at the 64th session of MEPC, and the following were adopted:

- A new Chapter 4 of MARPOL Annex VI will enter into force on January 1, 2013, including EEDI of new ships and SEEMP of all ships.
- Amendments to the 2012 Guidelines on the Method of Calculation of the Attained Energy Efficiency Design Index (EEDI) for New Ships (Resolution MEPC.212(63)), including the calculation of shaft generator power and shaft motor power.
- Amendments to the 2012 Guidelines on Survey and Certification of the Energy Efficiency.

In May 2013, the applicability issues of EEDI and SEEMP for different types of ships were discussed at the 65th session of MEPC, and the following resolutions were adopted.

- The session agreed that the ships without means of propulsion including platforms, drilling rigs and barges, etc., were not to meet the energy efficiency requirements.
- The application of EEDI for ships having ice-breaking capability.
- The EEDI requirements may be omitted for the cargo ships having ice-breaking capability based on the high installed power.
- The Draft 2013 Interim Guidelines for Determining Minimum Propulsion Power to Maintain the Maneuverability of Ships in Adverse Conditions.
- These interim guidelines are applied to bulk carriers, tankers, and combination carriers with the deadweight of equal or more than 20,000 DWT and conventional mode of propulsion during Phase 0. The minimum power guidelines were considered and approved.
- The 2013 Guidance on Treatment of Innovative Energy Efficiency Technologies were considered and approved.
- Guidelines for calculation of f_w , which is a nondimensional coefficient indicating the decrease of speed in representative sea conditions of wave height, wave frequency and wind speed (e.g., Beaufort Scale 6).
- The calculation methods and requirements of EEDI for ro-ro vehicle ships, ro-ro cargo ships, and ro-ro passenger ships.
- The development of relevant EEDI requirements for cruise passenger ships with non-conventional propulsion system.
- The calculation of EEDI for liquefied natural gas (LNG) carriers.
- The application of correction factors for general cargo ships.
- The application suggestion of assignments of three correction factors including f_j (correction factor to account for ship-specific elements)/ f_{IVSE} (structural enhancement correction factor)/ f_I (correction factor for ships equipped with cranes and other cargo-related gears) for general cargo ships, and the draft amendments to EEDI calculation guidelines.
- The sea trial methods and tank tests.
- The 2012 Guidelines on Survey and Certification of the Energy Efficiency Design Index

(EEDI) (Resolution MEPC.214(63)) were approved to be revised by specifying ITTC 7.5-04-01-01.1 part 1 and part 2 instead of ISO 15016:2002.

At the 66th session of MEPC in March 2014, the following resolutions were adopted.

1. Amendments to the 2012 Guidelines on the Method of Calculation of EEDI

- The use of Carbon Conversion Factor C_F for dual-fuel engines.
- The power weighting methods are not to apply for C_F but multiplying C_F -Gas and C_F -fuel oil by consumption of each fuel respectively at the EEDI load point.
- LNG carriers.
- The electrical efficiency should be taken as 91.3% for LNG carriers; alternatively, if the value more than 91.3% is to be applied, the method of ship measurement is to be adopted.
- The SFC of diesel-electrical propulsion systems should be taken as the value at 75% of MCR power.
- The methane leakage of LNG carriers is not to be taken into account in EEDI calculation, although the greenhouse gases emission caused.
- The application of correction factor f_j to account for ship-specific elements.
- The suggestion of correction factor f_j of EEDI calculation for refrigerated cargo carriers with ice class notations and that of editing revise of correction factor f_j of EEDI calculation for general cargo ships were added to the amendments of guidelines.
- The EEDI calculation of passenger ships with convention propulsion systems.
- The Attained EEDI of passenger ships with convention propulsion systems is to be calculated in accordance with the requirements in MARPOL Annex VI and the existing EEDI calculation guidelines.

The 2014 Guidelines on the Method of Calculation of EEDI were adopted at MEPC 66.

2. The amendments of Guidelines on Survey and Certification of EEDI

The 2014 Guidelines on Survey and Certification of EEDI were not adopted at this session, and would be considered at MEPC 67.

3. The amendments of MEPC.1/Circ.796 (Interim Guidelines on Calculation of f_w factor)

The progress of Interim Guidelines on Calculation of f_w factor developed by China and Japan was considered; further results were expected to be submitted and be added to guidelines on calculation of f_w .

4. The establishment of EEDI database

The proposal of establishing EEDI database was considered at this session; the goal and basic principles including security, publicity, and administrations of this database were confirmed; meanwhile, the minimum data parameters table for data collection, which based on the International Association of Classification Societies (IACS) version, was developed by the group.

At the 67th session of MEPC in October 2014, the relevant issues and resolutions of EEDI were as follows:

- The amendments suggestion of the Guidelines on Calculation of EEDI with dual-fuel engines.
- The calculation concept of EEDI with dual-fuel engines proposed by China was approved to a further consideration.
- The amendments of Guidelines on Survey and Certification of EEDI.
- The Amendments to Guidelines on Survey and Certification of EEDI including the main fuel definition of dual-fuel ships proposed by China were adopted.
- The guidelines for minimum power.
- The application duration of the 2013 Guidelines for Minimum Power in Adverse Conditions was approved to be extended to Phase 1.
- The communication group was approved to be set up for the technical consideration of EEDI Reference Line Value (RLV) during Phase 2 in MARPOL Annex VI.

- The basic content of revised data collection system was approved; the communication group was set up again to develop the full copy for data collection system of fuel consumption.

At the 68th session of MEPC in May 2015, the relevant issues and resolutions of EEDI were as follows:

- The data collection mechanism of fuel oil consumption for ships in operation.
- The consideration of EEDI data and EEDI in Article 21.6 of MARPOL Annex VI.
- The identified numbers of ships, which were only used by IMO secretariat, were approved to be added to EEDI database.
- The communication group was approved to be set up for further consideration of other data, such as the relevant information of innovative technology, main engine power, dimension parameters, ice class, etc. The results were to be taken into account for the setting and implement time of EEDI standards which were to be discussed at MEPC 69.
- The amendments of 2013 Interim Guidelines on the Minimum Installed Propulsion Power.
- The existing Interim Guidelines on the Minimum Installed Propulsion Power were amended, in which the requirements of level 1 for bulk carriers and oil tankers were enhanced.
- The amendments of 2014 Guidelines on Survey and Certification of EEDI (MEPC.254(67)) were adopted; the ISO 1506:2015 was added and approved to apply to the ships carrying out sea trial on or after September 1, 2015.
- The Amendments to 2014 Guidelines on Calculation of EEDI.
- Some specific ship types were approved to be further considered upon the suggestion of remaining the EEDI RLV during Phase 2 standards proposed by communication group.
- The consideration of EEDI technologies were to be continued based on the relevant data including innovative energy-saving technologies and dimension parameters, such as the names, working principles and performance of innovative energy-saving technologies, the length, breadth, and depth/draught of ships, or proportion of dimensions (L/B, L/D, etc.).
- The consideration of minimum propulsion power was approved to be separate from that of EEDI technologies.
- The consideration of recommendations to calculation method of the correction factor for ice-classed ships was delayed to MEPC 70,
- The method of calculation of ships with dual-fuel engines.
- The suggestion of EEDI calculation method of ships with dual-fuel engines proposed by China was approved generally, and China was invited to submit improved proposals to the next session by connecting with other interested countries and organizations.
- The Guidelines on Survey and Certification of EEDI concerning ISO 15016:2015.
- The regulations of water temperature measurement were contained in ISO 15016:2015, and the load variation factors for tank tests were considering by ITTC, there was no need to consider.
- The exemption conditions of SEEMP requirements.
- The MEPC circular, which contained the exemption suggestion of energy efficiency requirements for ships engaged on domestic voyages when engaged on international voyages once only, was approved.

The draft Amendments to Article 2.6 in 2014 Guidelines on Calculation of EEDI (MEPC.245(66)), which were proposed by organizations including IACS, were considered and approved. At the 69th session of MEPC in April 2016, the following resolutions were adopted:

At the 70th session of MEPC in October 2016, the Amendments to Guidelines of EEDI Calculation were developed.

- The consideration of EEDI RLV during Phase 2 standards.

- The requirements including reference lines, reduction factors, etc., of ship types other than ro-ro ships during Phase 2 were decided to maintain.
- The amendments to Guidelines on Calculation of EEDI.
- The amendments in which the EEDI was to be calculated with gas fuel as the nonessential fuel were adopted.
- The proposal of adding cubic capacity correction factors to EEDI calculation guidelines for wood cargo vessels was approved.
- The consideration of adding relevant information to IMO EEDI database.
- At this session, it was agreed that more IMO EEDI data were to be submitted including the main dimension, ship speed, installed power, and relevant summarization for application of energy-saving technologies, and this requirement was to come into force on April 1, 2017. For the data submitted, there was no need to supplement.
- The amendment of SEEMP Guidelines.

A Part II, as a guidance to develop data collection plans for fuel oil consumption, was added to the SEEMP Guidelines based on the Amendments to MARPOL Annex VI.

The resolution of Guidelines for the Development of SEEMP was issued.

At the 71st session of MEPC in July 2017, the following resolutions were adopted.

- The consideration of EEDI requirements for ro-ro passenger ships and ro-ro cargo ships.
- The amendments to Article 21 in MARPOL Annex VI were approved, in which the parameter value of reference lines for ro-ro passenger ships and ro-ro cargo ships was adjusted, in particular, the reference lines for ro-ro passenger ships with the deadweight more than 10,000 DWT and ro-ro cargo ships with that more than 17,000 DWT were set to be a constant value. The corresponding amendments to MARPOL Annex VI were to be adopted at MEPC 72.
- EEDI database: the suggestion of the definitions of relevant parameters, data rounding,

etc., proposed by secretariat was approved, so was the template of data submission. Meanwhile, in order to add EEDI data to MARPOL module of GISIS platform, it was agreed that the relevant information was to be reported to follow-up committee.

- The amendments to Interim Guidelines on the Minimum Installed Propulsion Power

Discussed by the Committee, the existing Guidelines on the Minimum Installed Propulsion Power, were approved to be extended to EEDI Phase 2. At the 72nd session of MEPC in April 2018, the following resolutions were adopted.

- The Amendments to EEDI requirements for ro-ro passenger and ro-ro cargo ships: The amendments to reference lines of ro-ro passenger ships and ro-ro cargo ships were approved and were to be entered into force on September 1, 2019. The segmented reference lines for ro-ro passenger ships with the deadweight more than 10,000 DWT and ro-ro cargo ships with that more than 17,000 DWT were to be developed for use from Phase 2 (2020.1.1). Meanwhile, these amendments could be put into effect earlier by Administrations of every country.
- The EEDI requirements for ice-classed ships: The amendments to Article 19.3 of MARPOL Annex VI were to be pointed to the Polar Code, the original clause “The EEDI requirements may be omitted for the ice-classed ships with an ice class of equal or higher than IACS PC5 (or equal ice class)” was to be revised as “The Article 20 and 21 are not applicable to the ships of A category in the Polar Code.” Meanwhile, the definition of cargo ships having ice-breaking capability in Annex VI was suggested to be deleted, and that of Polar Code to be added.

Calculation Method of EEDI

Calculation Formula

The Attained EEDI is calculated by the following formula:

$$EEDI_a = \left(\prod_{j=1}^n f_j \right) \left(\sum_{i=1}^{n_{ME}} P_{ME(i)} \cdot C_{FME(i)} \cdot SFC_{ME(i)} \right) + (P_{AE} \cdot C_{FAE} \cdot SFC_{AE})$$

$$+ \left(\left(\prod_{j=1}^n f_j \cdot \sum_{i=1}^{n_{PTI}} P_{PTI(i)} - \sum_{i=1}^{n_{eff}} f_{eff(i)} \cdot P_{AEeff(i)} \right) C_{FAE} \cdot SFC_{AE} \right) - \left(\sum_{i=1}^{n_{eff}} f_{eff(i)} \cdot P_{eff(i)} \cdot C_{FME} \cdot SFC_{ME} \right)$$

$$\frac{f_i \cdot f_c \cdot f_w \cdot W \cdot V_{ref}}{(1)}$$

where:

$EEDI_a$ is the attained EEDI value, measured in g/(t·nm).

n is the number of power correction factors.

f_j is the power correction factor.

n_{ME} is the number of main engines.

$P_{ME(i)}$ is the power of each main engine, measured in kW.

$C_{FME(i)}$ is the carbon conversion factor of fuel for each main engine, selected according to Table 1.

$SFC_{ME(i)}$ is the specific fuel consumption of each main engine, measured in g/kW h.

P_{AE} is the power of auxiliary engines, measured in kW.

C_{FAE} is the carbon conversion factor of fuel for auxiliary engines according to Table 1.

SFC_{AE} is the specific fuel consumption of auxiliary engines, measured in g/kW h.

n_{PTI} is the number of shaft motors.

$P_{PTI(i)}$ is the power of each shaft motor, measured in kW.

n_{eff} is the number of new energies and new technologies adopted.

$f_{eff(i)}$ is the energy efficiency factor of each innovative energy-efficient technology.

$P_{AE\ eff(i)}$ is the auxiliary power reduction due to innovative electrical energy-efficient technology measured at P_{ME} , measured in kW.

$P_{eff(i)}$ is the output of the innovative mechanical energy-efficient technology for propulsion at 75% main engine power, measured in kW.

C_{FME} is the carbon conversion factor of fuel for main engines.

SFC_{ME} is the specific fuel consumption of main engines, measured in g/kW h.

f_i is the capacity correction factor.

f_c is the cubic capacity correction factor.

f_w is the speed loss coefficient.

W is the capacity.

V_{ref} is the ship speed, measured in knot. Note 1: If part of the normal maximum sea load is provided by shaft generators, for that part of the power, SFC_{ME} and C_{FME} may be used instead of SFC_{AE} and C_{FAE} . Note 2: If $P_{PTI(i)} > 0$, the weighted average value of $(SFC_{ME} \cdot C_{FME})$ and $(SFC_{AE} \cdot C_{FAE})$ is to be used for calculation of P_{eff} .

Energy Efficiency Regulations from IMO, Table 1 Carbon conversion factor

No.	Type of fuel	Reference	Carbon content	C_F
1	Diesel/gas oil	ISO 8217 grades DMX through DMC	0.8744	3.206
2	Light fuel oil (LFO)	ISO 8217 grades RMA through RDM	0.8594	3.151
3	Heavy fuel oil (HFO)	ISO 8217 grades RME through RMK	0.8493	3.114
4	Liquefied petroleum gas (LPG)	Propane	0.8182	3.000
		Butane	0.8264	3.030
5	Liquefied natural gas (LNG)	—	0.7500	2.750
6	Methanol	—	0.3750	1.375
7	Ethanol	—	0.5217	1.913

The C_F value for different type of fuel is as follows:

Ship Speed (V_{ref})

V_{ref} is the ship speed on deep water in the condition corresponding to the capacity as defined in paragraph 2.2.3 (in case of passenger ships and cruise passenger ships, this condition is to be summer load draught as provided in paragraph 2.2.4) at the power of the main engine(s) as defined in paragraph 2.2.5.1 and assuming the weather is calm with no wind and no waves.

Capacity

Capacity is defined as follows for different ship types:

- For bulk carriers, tankers, gas carriers, LNG carriers, ro-ro cargo ships (vehicle carriers), ro-ro cargo ships, ro-ro passenger ships, refrigerated cargo carriers, general cargo ships, combination carriers and offshore supply vessels, deadweight (DWT) is to be used as capacity.
- For passenger ships and cruise passenger ships, gross tonnage (GT) in accordance with the International Convention of Tonnage Measurement of Ships 1969, annex I, regulation 3, is to be used as capacity.
- For containerships, 70% of the deadweight (DWT) is to be used as capacity. EEDI values for containerships are calculated as follows: Attained EEDI value is to be calculated using 70% DWT in accordance with EEDI formula; required EEDI value is to be calculated using 100% DWT in accordance with reference line formula.

Deadweight (DWT)

Deadweight means the difference in tonnes between the displacement of a ship in water of relative density of 1025 kg/m³ at the summer load draught and the lightweight of the ship.

Power of the Main Engines (P_{ME})

P_{ME} is 75% of the maximum continuous rating (MCR) for each main engine. The MCR value specified on the Engine International Air

Pollution Prevention Certificate (EIAPP) is to be used for calculation. If the main engines are not required to have an EIAPP certificate, the MCR value on the nameplate is to be used for calculation. For LNG carriers having diesel electric propulsion system, P_{ME} is to be calculated by the following formula:

$$P_{ME(i)} = 0.83 \times \frac{MPP_{Motor(i)}}{\eta_{(i)}} \quad (2)$$

where $MPP_{Motor(i)}$ is the rated output of motor specified in the certified document, $\eta_{(i)}$ is to be taken as the product of electrical efficiency of generator, transformer, converter, and motor, taking into consideration the weighted average as necessary.

In case where a shaft generator is installed, if the maximum allowable deduction for the calculation of $P_{ME(i)}$ is not more than P_{AE} as defined in paragraph 2.2.5.4, $P_{ME(i)}$ is to be calculated by the following formula, and if the power of engine is higher than the maximum design power of propulsion system, the value of $P_{ME(i)}$ is to be 75% of that maximum design power of propulsion system.

$$P_{ME(i)} = 0.75 \times (MCR_{ME(i)} - P_{PTO(i)}) \quad (3)$$

Fig. 1 gives guidance for determination of $P_{ME(i)}$.

In case where shaft motor(s) are installed, P_{ME} is to be calculated by the following formula at which V_{ref} is measured:

$$P_{ME} = \sum P_{ME(i)} + \sum P_{PTI(i),shaft} \quad (4)$$

$$\sum P_{PTI(i),shaft} = \sum (P_{PTI(i)} \cdot \eta_{PTI(i)}) \cdot \eta_{gen}$$

where $P_{PTI(i),shaft}$ is the output of each shaft motor, measured in kW; $\eta_{PTI(i)}$ is the efficiency of each shaft motor; η_{gen} is the weighted average efficiency of the generators; P_{ME} is higher than 75% of the maximum design power of propulsion system, then 75% of the maximum design power of propulsion system is to be used as P_{ME} .

Energy Efficiency Regulations from IMO,
Fig. 1 Determination of the power P_{ME} of a main engine

E

Shaft Generator Power P_{PTO}

In case where a shaft generator is installed, the shaft generator power $P_{PTO(i)}$ is 75% of the rated electrical power output for each shaft generator. In case where shaft motor(s) are installed, $P_{PTI(i)}$ is 75% of the rated power consumption of each shaft motor divided by the weighted average efficiency of the generator(s). In case of combined PTI/PTO , the normal operational mode at sea will determine which of these is to be used in the EEDI calculation. For example, if this combined system is used as a shaft generator for ships in normal operation at sea, the P_{PTO} parameter is to be used in the EEDI calculation formula and P_{PTI} equals 0. The shaft motor's chain efficiency may be taken into consideration instead of the weighted average efficiency of the generator to account for the energy losses in the equipment from the switchboard to the shaft motor, if the chain efficiency of the shaft motor is given in a verified document.

Auxiliary Engine Power P_{AE}

P_{AE} is the required auxiliary engine power to supply normal maximum sea load including necessary power for propulsion machinery/systems and accommodation, for example, main engine pumps, navigational systems and equipment, and living on board, but excluding the power not for propulsion machinery/systems, for example, thrusters, cargo pumps, cargo gear, ballast pumps, maintaining cargo, for example, reefers and cargo hold fans, in the condition where the ship engaged in voyage at the speed (V_{ref}) under the maximum design load condition (Capacity).

P_{AE} used for the calculation of Attained EEDI of ships is to be calculated by the following experience-based formulae:

- For ships with a main engine power of 10,000 kW or above, P_{AE} is defined as:

$$P_{AE} = \left[0.025 \times \left(\sum_{i=1}^{n_{ME}} MCR_{MEi} + \frac{\sum_{i=1}^{n_{PTI}} P_{PTI(i)}}{0.75} \right) \right] + 250 \quad (5)$$

(b) For ships with a main engine power below 10,000 kW, P_{AE} is defined as:

$$P_{AE} = 0.05 \times \left(\sum_{i=1}^{n_{ME}} MCR_{MEi} + \frac{\sum_{i=1}^{n_{PTI}} P_{PTI(i)}}{0.75} \right) \quad (6)$$

(c) For passenger ships and cruise passenger ships, where the P_{AE} value calculated by above formulae is significantly different from the total power used at the speed V_{ref} , the P_{AE} value is to be estimated by the consumed electric power (excluding propulsion) in conditions when the ship is engaged in a voyage at the reference speed (V_{ref}) as given in the electric power table, divided by the average efficiency of the generator(s) weighted by power.

Propulsion power reduced by using the innovative technology $P_{eff(i)}$, which is the output power of the innovative mechanical energy-efficient technology for propulsion at 75% main engine power. In case of a ship equipped with a dual-fuel engine or a number of engines, the C_{FME} and SFC_{ME} are to be the power weighted average value of all the main engines.

Auxiliary power reduced due to innovative technology $P_{AE\ eff(i)}$, which is the auxiliary power reduced due to the adoption of innovative electrical energy-efficient technology when the ship is in the $P_{ME(i)}$ state.

Specific Fuel Consumption (SFC)

The certified specific fuel consumption (SFC) of the engines is defined as follows:

- For engines certified to the E2 or E3 duty cycles, the engine SFC ($SFC_{ME(i)}$) is that recorded in the test report included in a NO_x technical file for the engine(s) at 75% of MCR power or its torque rating.
- For engines certified to the D2 or C1 duty cycles, the engine SFC ($SFC_{AE(i)}$) is that recorded in the test report included in a NO_x technical file at the engine(s) at 50% of MCR power or its torque rating.
- For conventional passenger ships and cruise passenger ships, where the P_{AE} value calculated by the above procedures is significantly different from the total power used at normal seagoing, the SFC (SFC_{AE}) of the auxiliary generators is that recorded in the test report included in a NO_x technical file for the engine (s) at 75% of MCR power or its torque rating. For those engines that do not have an EIAPP certificate because its power is below 130 kW, the SFC specified by the manufacturer and endorsed by the Administration or China Classification Society (CCS) is to be used.

Correction Factor

Power correction factor f_j : f_j is a correction factor to account for ship-specific design elements. For ice-classed ships, this factor is to be taken as the greater value of f_{j0} and $f_{j,min}$ as tabulated in Table 2, but not to be greater than 1.0.

The factor f_j for shuttle tankers with propulsion redundancy and having a deadweight of 80,000–160,000 tonnes is to be $f_j = 0.77$. The shuttle tankers with propulsion redundancy are tankers used for loading of crude oil from offshore installations and equipped with dual-engine and twin-propellers need to meet the requirements for dynamic positioning and redundancy propulsion class notation.

Capacity correction factor f_i : f_i is the capacity correction factor to account for any technical/regulatory limitation on capacity, and can be assumed 1.0 if no necessity of the factor is granted. For ice-classed ships, this factor is to be taken as the lesser value of f_{i0} and $f_{i,max}$ as tabulated in Table 3, but not to be less than 1.0.

For ships with voluntary structural enhancements, f_{VSE} is to be expressed as follows:

Energy Efficiency Regulations from IMO, Table 2 Correction factor f_j for ice-classed ships

Ship type	f_{j0}	$f_{j,min}$ depending on ice class			
		IC	IB	IA	IA Super
Tanker	$\frac{0.308L_{pp}^{1.920}}{\sum_{i=1}^{nME} P_{ME(i)}}$	$0.70L_{pp}^{0.06}$	$0.45L_{pp}^{0.13}$	$0.27L_{pp}^{0.21}$	$0.15L_{pp}^{0.30}$
Bulk carrier	$\frac{0.639L_{pp}^{1.754}}{\sum_{i=1}^{nME} P_{ME(i)}}$	$0.87L_{pp}^{0.02}$	$0.73L_{pp}^{0.04}$	$0.58L_{pp}^{0.07}$	$0.47L_{pp}^{0.09}$
General cargo ship	$\frac{0.0227L_{pp}^{2.48}}{\sum_{i=1}^{nME} P_{ME(i)}}$	$0.67L_{pp}^{0.07}$	$0.56L_{pp}^{0.09}$	$0.43L_{pp}^{0.12}$	$0.31L_{pp}^{0.16}$

Note 1: L_{pp} is the length between perpendiculars

Note 2: B1*, B1, B2 and B3 are ice class notations specified in CCS Rules for Classification of Sea-going Steel Ships, which correspond to IA Super, IA, IB, IC as specified in Finish and Swedish Ice Class Rules (FSICR)

E

Energy Efficiency Regulations from IMO, Table 3 Correction factor f_i for ice-classed ships

Ship type	f_{i0}	$f_{i,max}$ depending on ice class			
		IC	IB	IA	IA Super
Tanker	$\frac{0.00138L_{pp}^{3.331}}{capacity}$	$1.27L_{pp}^{-0.04}$	$1.47L_{pp}^{-0.06}$	$1.71L_{pp}^{-0.08}$	$2.10L_{pp}^{-0.11}$
Bulk carrier	$\frac{0.00403L_{pp}^{3.123}}{capacity}$	$1.31L_{pp}^{-0.05}$	$1.54L_{pp}^{-0.07}$	$1.80L_{pp}^{-0.09}$	$2.10L_{pp}^{-0.11}$
General cargo ship	$\frac{0.0377L_{pp}^{2.625}}{capacity}$	$1.28L_{pp}^{-0.04}$	$1.51L_{pp}^{-0.06}$	$1.77L_{pp}^{-0.08}$	$2.18L_{pp}^{-0.11}$
Container ship	$\frac{0.1033L_{pp}^{2.329}}{capacity}$	$1.27L_{pp}^{-0.04}$	$1.47L_{pp}^{-0.06}$	$1.71L_{pp}^{-0.08}$	$2.10L_{pp}^{-0.11}$
Gas carrier	$\frac{0.0474L_{pp}^{2.590}}{capacity}$	$1.25L_{pp}^{-0.04}$	$1.60L_{pp}^{-0.08}$	$2.10L_{pp}^{-0.12}$	1.25

$$f_{iVSE} = \frac{DWT_{reference\ design}}{DWT_{enhanced\ design}}$$

$$= \frac{\Delta_{ship} - lightweight_{reference\ design}}{\Delta_{ship} - lightweight_{enhanced\ design}} \quad (7)$$

where f_{iVSE} is the capacity correction factor of ships with voluntary structural enhancements; $DWT_{reference\ design}$ is the deadweight prior to application of the structural enhancements, measured in t; $DWT_{enhanced\ design}$ is the deadweight following the application of voluntary structural enhancements, measured in t; Δ_{ship} is the displacement of a ship, measured in t, for this calculation, the same displacement (Δ) is to be taken for reference and enhanced designs; $lightweight_{reference\ design}$ is the lightweight of a ship prior to application of the structural enhancements, measured in t; $lightweight_{enhanced\ design}$ is the lightweight of a ship following the application of voluntary structural enhancements, measured

in t. For this calculation, a change of material (e.g., from aluminum alloy to steel) or a change in grade of the same material (e.g., in steel types, grades, properties and conditions) between reference design and voluntarily enhanced design is not to be allowed for the f_{iVSE} calculation.

For bulk carriers and oil tankers that are constructed according to Common Structural Rules (CSR) and assigned the CSR notation, the following capacity correction factor f_{iCSR} is to be used:

$$f_{iCSR} = 1 + \left(0.08 \times \frac{LWT_{CSR}}{DWT_{CSR}} \right) \quad (8)$$

where f_{iCSR} is the correction factor to account for any technical/regulatory limitation on capacity for ships which are constructed according to CSR; LWT_{CSR} is the lightweight of ships which are constructed according to CSR, measured in t; DWT_{CSR} is the deadweight of ships which are

constructed according to CSR, measured in t. For other ship types not included in the Table 3, f_i is to be taken as 1.0.

Cubic Capacity Correction Factor f_c

f_c is to be taken as 1.0 generally. For chemical tankers, the cubic capacity correction factor f_c is to be taken as the following formula for $R < 0.98$, or $f_c = 1.00$ for $R \geq 0.98$. For gas carriers that are constructed or adapted to carry liquefied natural gas in bulk and with propulsion systems directly driven by diesel engines, the f_c is to be:

$$f_c = R^{(-0.7)} - 0.014, f_c = R^{-0.56} \quad (9)$$

where R is the ratio of the ship's DWT (in tonnes) to the total cubic capacity (in m^3) of its cargo tanks.

Speed Loss Coefficient f_w

f_w is to be taken as 1.0 generally. Where the Owner requests on a voluntary basis the application of f_w , the Attained EEDI value using f_w is to be referred to Attained EEDI_{weather} and confirmed by the Administration, and indicated in the related certificate. f_w is to be determined as follows:

- f_w can be determined by conducting the ship-specific simulation of its performance at representative sea conditions. The simulation methodology is to be that as prescribed in the Guidelines developed by IMO and the method and outcome for an individual ship is to be verified by the Administration or CCS.
- In case where the simulation is not conducted, f_w value is to be taken from the "Standard f_w " table/curve prescribed in the Guidelines developed by IMO.

Note: Refer to Interim Guidelines for the calculation of the coefficient f_w for decrease in ship speed in a representative sea condition for trial use, approved by the Organization and circulated by MEPC.1/Circ.796.

Energy Efficiency Factor f_{eff}

f_{eff} is the availability factor of each innovative energy efficiency technology. f_{eff} for waste energy recovery system is to be taken as 1.0.

Verification of EEDI

Verification Process

Verification of the EEDI is to be conducted on two stages: preliminary verification at the design stage, and final verification at the sea trial. The verification procedure is shown in Fig. 2.

Preliminary Verification at the Design Stage

For the preliminary verification at the design stage, an application for the preliminary verification and an EEDI technical file containing the necessary information for the verification and other relevant background documents are to be submitted.

Prior to submitting the application for the preliminary verification of EEDI, the ship designer and/or the shipbuilder is to complete basic design of the ship and carry out a tank test, the Attained EEDI is to be calculated in accordance with the calculation methods in section "The Considering Procedure of MEPC for EEDI" above using the obtained parameters.

If dual fuel engines are installed, and gas fuel will primarily be used as fuel on the ship, the following information is to be provided:

- The use of boil-off gas or capacities of the gas fuel storage tanks, and the capacities of fuel storage tanks
- Arrangements of bunkering facilities for gas fuel in the intended operational area of the ship

The specific fuel consumption (SFC) of the main and auxiliary engines is to be quoted from the approved NO_x technical file; in case the NO_x technical file has not been approved at the time of the application for the initial survey, the test reports provided by manufacturers are to be used. In this case, at the time of the sea trial verification, a copy of the approved NO_x technical file and documented summary of the correction calculations are to be submitted.

The power curves used for the preliminary verification at the design stage are to be based on reliable results of the tank test. A tank test for an individual ship may be omitted based on technical justifications such as availability of the results of tank tests for ships of the same type. In addition, omission of tank tests is acceptable for a ship for

Energy Efficiency Regulations from IMO,
Fig. 2 Verification procedure

which sea trials will be carried out under the condition of specified draught corresponding to the capacity, upon agreement of the ship owner and shipbuilder and with approval of the verifier. For ensuring the quality of tank tests, the quality system of the International Towing Tank Conference (ITTC) is to be taken into account.

Final Verification of the Attained EEDI at Sea Trial

Sea Trial Conditions

At sea trial, the draught is to be set according to the section “[The Considering Procedure of MEPC for EEDI](#)” above at the speed V_{ref} .

Preparation Prior to Sea Trial

Prior to the sea trial, the following documents are to be submitted by the applicant:

- The procedure of speed testing, including all items to be measured and corresponding measurement methods to be used for developing power curves under sea trial conditions
- The final displacement table (or hydrostatic table) and the measured lightweight at inclining test, or a copy of the deadweight survey report
- A copy of NO_x technical file, if not submitted for the preliminary verification

Sea Trial Verification Requirements

Prior to the sea trial, the following conditions are to be confirmed:

- Prior to the sea trial, the ship is to be under seaworthy condition, and the measured power equipment are to be under good or normal condition.

- Draft and trim are to be confirmed by the draft measurements taken prior to the speed testing. The draft and trim are to be as close as practical to those at the assumed conditions used for estimating the power curves.
- Sea conditions are to be measured in accordance with ISO 15016:2002 or the equivalent.
- Ship speed is to be measured in accordance with ISO 15016:2002 or the equivalent and at more than two points of which range includes the main engine at 75% of MCR power.
- Output power measurement.
- The shipbuilder is to develop power curves based on the measured ship speed and the measured output of the main engine at sea trial.
- The shipbuilder is to compare the power curves obtained as a result of the sea trial and the estimated power curves at the design stage; in case differences are observed, the Attained EEDI is to be recalculated in accordance with the power curves at the sea trial.
- In case where the finally determined deadweight/gross tonnage differs from the designed deadweight/gross tonnage used in the EEDI calculation at the design stage, the ship owner or shipbuilder is to recalculate the Attained EEDI using the finally determined deadweight/gross tonnage. The finally determined gross tonnage is to be confirmed in the Tonnage Certificate of the ship.
- In case where the Attained EEDI is calculated at the preliminary verification by using SFC based on the manufacturer's test report due to the nonavailability at that time of the approved NO_x Technical file, the Attained EEDI is to be recalculated by using SFC in the approved NO_x technical file.
- The EEDI technical file is to be revised, as necessary, by the shipbuilder or the diesel engine manufacturer, taking into account the results of sea trial. Such revision is to include, as applicable, the adjusted power curve based on the results of sea trial, the final determined deadweight/gross tonnage and SFC described in the approved NO_x technical file, and the recalculated Attained EEDI based on these modifications.
- The EEDI technical file, if revised, is to be submitted to the verifier for the confirmation

that the revised Attained EEDI is calculated in accordance with the calculation methods in section [“The Considering Procedure of MEPC for EEDI”](#) above.

[Environmental impact assessment \(EIA\)](#)

Definition

Development and environmental protection are often in conflict, and the purpose of an **environmental impact assessment (EIA)** is to contribute toward the decision-making process by resolving and preventing conflicts between the two (Environmental Impact Assessment Ordinance 1998). EIA is a system for forecasting future effects

of a new project on the environment, aimed to minimize negative effects. EIA is also a tool to assess ecological implications of projects, policies, and physical plans and prevent future environmental problems in an action in advanced manner.

Scientific Fundamentals

Sustainable development is development targeted to meet the needs and interests of the present generation without compromising those of the future generations. **EIA** system is a decision-making tool to prompt sustainable development by informing decision-makers to strike a balance between development and protection, and it requires legal compliance enforcement support to govern the issuing of **environmental permits (EP)**. The EIA system helps to achieve better environmental outcomes through identifying and evaluating potential impact of development on the environment alongside the necessary prevention and mitigation measures at the early stages of project planning and design, by applying the cardinal principle of EIA, i.e., **avoidance-minimization-mitigation** (Fig. 1). After screening and scoping, an EIA report identifies and predicts likely environmental and socioeconomic impacts and evaluates their significance. It should then develop measures to avoid, reduce, or compensate for impacts and attempt to offset any environmental damage. An EIA report usually includes an **Environmental Monitoring and Auditing (EM&A) Manual** (Environmental Impact Assessment Ordinance 1998), as EM&A is the critical implementation and follow-up stage after the project (Morrison-Saunders et al. 2001). Using the EIA system in Hong Kong as an example (Wood and Coppell 1999), the processes involved in conducting an EIA for a proposed project are described in the following sections.

EIA Process

Screening and Scoping of a Project

While the exact process of an EIA and corresponding legal frameworks may differ

Environmental Impact Assessment System,

Fig. 1 An illustration that depicts the environmental impact of a developmental project, with residual impact after mitigations

between countries around the world, the role and purpose of an EIA is similar at its core. EIAs are intended to identify the potential impacts of a project in the early planning stages, as well as alternatives or measures to minimize environmental impact, which serve to inform decision-makers before proceeding with the project (Fig. 1).

The EIA system in Hong Kong is regulated by the **Environmental Impact Assessment Ordinance (EIAO)**. Under the Ordinance, the first stages of an EIA involve **screening and scoping**. Screening is the process of determining whether an EIA is required for a proposed project. To address this, project proponents are required to provide a Project Profile to enable the Director of **Environmental Protection Department (EPD)**, who enforces the Ordinance, to make informed decisions. The Project Profile should provide clear analysis on the scope of environmental issues of the project, issues and anticipated outcomes of the project, and technical and procedural requirements to be addressed in EIA. If there is no adverse impact anticipated in carrying out the proposed project, such project may be exempted from an **EIA Study/Report** and project proponents may directly apply for an environmental permit, which indicates approval by authorities to proceed with the project further (Fig. 2).

In most cases, a development project is likely to result in significant irreversible impact that needs to be addressed by an EIA Study before

proceeding (Fig. 2). Authorities including developers and experts will usually define key issues with the proposed project and possible impact in greater detail, known as scoping, in the form of an **EIA Study Brief**. The Study Brief should define the purpose and objectives of the EIA Study/Report, specifying the scope of environmental issues that need to be addressed including the type, scale, time frame, location, emissions, discharges, waste generation, destruction, alteration, or environmental changes that may result from the project. It should also highlight other requirements such as methodologies to follow, relevant experience and complaints from previous EIAs and environmental studies, time schedule, public participation, and budget issues. Depending on the nature of proposed project, the Study Brief should also stipulate the geographical and temporal boundaries of the project, define issues related to the combined impacts of projects and cumulative impacts of existing and planned developments in the vicinity of the project, and specify the duration of validity of the Study Brief itself as well as the number of EIA Reports and Executive Summary required. The Study Brief serves to inform the Project Proponent the issues to be addressed in the subsequent EIA Study/Report (Fig. 2).

EIA Study and Report

The next stage of EIA involves conducting the relevant impact assessments to generate a full EIA

Overview of the EIAO Process

E

Environmental Impact Assessment System, Fig. 2 An overview of the EIA process. Revised from training manual for the EIA mechanism by Hong Kong EPD (Wood and Coppel 1999)

Study/Report, following the scopes of EIA (as specified in the Technical Memorandum of the Ordinance). The objective of an EIA Study is to describe the proposed project and the associated works and their impact, identifying the elements of the community and sensitive receivers that are likely to be affected due to emission sources across potentially affected areas. The EIA Study should also identify and quantify the significance of the impact resulting from the project in terms of the potential losses and propose the provision of infrastructure or mitigation to minimize the pollution and environmental disturbance during construction and operation of the project. Residual effects after mitigation should also be considered. Finally, the EIA Study should look to provide appropriate monitoring and auditing design as a follow-up to the project. As a result, the EIA Study is often prepared by consultants and academics within a multidisciplinary team due to the need for expertise in determining whether standards and criteria in specific technical requirements, as defined by previous studies and enforced by legislation of the region, have been met.

Environmental Baseline Studies

Environmental baseline studies refer to the collection of baseline information on biophysical, social, and economic aspects of a project area. Project area refers to the area where environmental effects and impacts are felt (the site of the project, its access, and any other areas likely to be impacted) during construction or operational stages or decommissioning of a project. The purpose of environmental baseline studies is to reinforce current project's impact assessment by providing a description of the status and trends of environmental factors, to which identified and predicted impact and changes resulting from the project can be compared to and evaluated in terms of importance. Through monitoring, environmental baseline studies also provide a means of detecting actual changes after the project has been initiated. A good environment baseline enables potential environmental impacts from a project to be predicted and evaluated and is the foundation of an EIA, resembling the piling of a building. Baseline information plays a critical role in the EIA process as it is necessary to determine the existing environmental conditions on the site

and identify existing receivers and communities affected, habitats, and resources which are vulnerable to anticipated changes before any further project commences.

Major data sources and methods of collection are two critical issues in the environmental baseline studies. Impact assessment is fundamentally the prediction of the effect of a project based on established baseline information. To achieve this, a combination of accurate primary data sources and reliable secondary data sources is required. Primary data are results from the field or laboratory data collected and analyzed directly. In contrast, secondary data are data collected indirectly from previous published records or documents such as project documents, village profile, maps, photos, and Internet sources. Common methods of data collection include literature review, map interpretation, checklists (e.g., scaling and questionnaire checklists, matrices, etc.), and resource-based methods, such as scientific instruments and techniques (inventory, species area curve, sampling techniques, etc.). A good baseline information should consider multiple data sources to form an overview on the environment. The impact on a project area due to the proposed project can then be modeled using primary data and compared with the baseline information. For example, meteorological condition data can be used to model air quality impacts in assessments.

Impact Assessment and Mitigations

The impacts which may result from a proposed project are assessed comprehensively under different criteria. In most EIA reports, possible impact on the environment include aspects of air quality, noise, water quality, waste management implications, terrestrial ecology, marine ecology, fisheries impact assessment, hazard assessment, socioeconomic impact, cultural heritage and anthropological impact, and landscape and visual impact. For each of the identified impact, the EIA Report should clearly indicate the relevant environmental legislation, policies, plans, standards, and criteria that referred to in the assessment. The Report should then provide a description of the environment of the project area and identify

the environmental impact as well as the sensitive receivers of the impact through construction and operation phases of the project. The assessment methodologies, baseline information, evaluation and mitigation of impact, and residual impact for both construction and operation phases should then be clearly described. Finally, environmental monitoring and auditing design should be proposed for each of the assessed impact, often standalone in an **EM&A Manual** which supplements the EIA Study/Report.

Project Monitoring and Auditing

As a follow-up of the EIA, project monitoring and auditing covers both the construction stage and operational stage of the development project, and it spans a much longer time period than the completion of the EIA Report. Project monitoring and auditing can help to verify that the EIA predictions and assumptions are valid, monitor the actual environmental performance to preempt impacts before breaching established criteria, ensure that mitigation measures are properly and timely implemented, and improve future EIA predictions.

In general, EM&A shall be required if the project has the potential of causing environmental impacts which are or are likely to be prejudicial to the health or well-being of people, the flora, fauna, or ecosystem if the recommended measures are not properly implemented. EM&A should also be required if it involves mitigation measures of which the effectiveness may require a long period to establish, e.g., compensatory planting of trees, an unproven technology, or mitigation measure, or is based on a new technique or model, or there is other uncertainty about design assumptions and/or the conclusions, or project scheduling is subject to change such that significant environmental impacts could result.

In Hong Kong, the issuing of EP may impose requirements for monitoring to verify predictions or the effectiveness of measures as conditions. The specifications are derived from the EIA Study carried out by project proponents. In an approved EM&A Manual, EM&A programs required will be clearly defined including the monitoring parameters, frequency, duration, and

monitoring station locations. Similar to the EIA Study, EM&A work should also be carried out by qualified personnel.

In the implementation of EM&A, the proponent is responsible for implementing the necessary mitigation measures, ensuring the expected performance is achieved, and taking necessary remedial measures to address unanticipated or unacceptable impacts. The steps in developing a monitoring program should be methodical. The scope and objectives of the monitoring program should be identified to decide what and how data are to be collected and analyzed. The area to be monitored should be clearly defined as well as the follow-up actions to be carried out. In a multi-disciplinary team, responsibilities of each party involved should be clearly defined.

Key Elements of an EM&A Program

The key elements of an EM&A program include baseline monitoring data, impact/compliance monitoring program, action/limit levels and event/action plan, reporting procedures, and implementation mechanism. Environmental monitoring refers to the systematic collection of environmental data through a series of repetitive measurements. Two different monitoring activities are involved in the process: baseline monitoring and impact/compliance monitoring.

Baseline monitoring refers to the measurement of environmental parameters during a representative pre-project period for the purpose of determining the nature and ranges of natural variation. Baseline monitoring can also be applied to establish, where appropriate, the nature of change.

Impact/compliance monitoring involves the measurement of environmental parameters during project construction and implementation to detect changes in these parameters which can be attributed to the project. This can serve to ensure that regulatory requirements are in place, and standards are met.

Aside from monitoring, environmental auditing is an equally important part of the EM&A program. Audit is a term taken from financial accounting to infer the notion of verification of practice and certification of data. **Environmental audit** is the process of verification that all or selected parameters

measured by an environmental monitoring program are in compliance with regulatory requirements, internal policies and standards, and established environmental quality performance limits. Environmental audit involves the process of comparing project impact predictions with actual impacts for the purpose of assessing the accuracy of predictions, the effectiveness of the environmental management system, practices and procedures, and determining the degree and scope of any necessary remedial measures in case of exceedances of compliance.

To supplement the auditing process, **action levels** are the levels of parameters which if exceeded are indicative of a deteriorating ambient environmental quality. Appropriate remedial actions may be necessary to prevent the environmental quality from going beyond the limit levels, which would be unacceptable. **Limit levels** are the levels stipulated in relevant pollution control ordinances, or the Hong Kong Planning Standards and Guidelines, or other appropriate criteria established by EPD for a particular project, beyond which the works should not proceed. Details in legislation may differ between regions. In an EM&A program, the **event/action plan** specifies the responsibilities of each key player, and “what” action to be undertaken by “whom” in case of exceedance in action/limit levels. The normal action for single exceedance of action level is to increase the monitoring frequency in order to identify the cause of problems and to be subsequently addressed.

Key Applications

The difference between an EIA and Strategic Environmental Assessment lies in application. EIA is used to identify the environmental and social impacts of a proposed project, usually by individuals and companies, prior to decision-making in order to predict environmental impacts at an early stage in project planning and design. In contrast, Strategic Environmental Assessment is used at the policy, planning, and programming levels. Strategic Environmental Assessment is a systematic process for evaluating the

environmental implications of a proposed policy, plan, or program and provides means for looking at cumulative effects and appropriately addresses them at the earliest stage of decision-making alongside economic and social considerations. In any case, early consultation and involvement of EIA professionals in a project's conceptual development, planning, and design is the recommended approach, as it can often lead to a better project design with the consideration of sensitive receivers and avoidance of impacts. Having to revise a poorly designed project plan at a later stage is inefficient and can be a major setback for any project and its stakeholders.

Since the publication of *Silent Spring* by Rachel Carson back in 1963, the issue of environmental protection has been brought up and slowly developed into a global topic which demanded action (Environmental Impact Assessment Ordinance 1998). There is a desperate need for sustainable development which meet present needs without compromising the future generations. As a result, environmental impact assessment is a well-developed, organized system of evaluating the nature and extent of environmental impact arising from construction and operation of any proposed development project. It provides a comprehensive overview of potential impact on not only the environment but also at the socio-economic level, concerning human health and cultural impact, to aid the decision-making process and optimize the balance between development and protection with mitigation measures. The philosophy of preventing impact from happening instead of reacting to environmental damage which already occurred proved to be a more effective approach in addressing environmental problems around the world (LIM 1988).

Definition

Environmental Perception is one of the most basic functions of underwater vehicles, and it is the method for underwater vehicles to recognize their environment. Through environmental perception technology, underwater vehicles can determine their own location and identify the distribution of surrounding objects, targets, or obstacles. It is the basis for realizing the navigation and path planning of underwater vehicles.

Scientific Fundamentals

The development of oceans and the associated competition have become the strategic focus of many countries, and these goals have become pursued with increasing fierceness. Compared with other underwater vehicles that can be

explored, underwater vehicles have numerous advantages such as underwater payload capacity, maneuverability, and depth of activity. In a variety of marine technologies, autonomous underwater vehicles (AUVs) can be used for comprehensive surveys and studies in areas where the depth cannot be reached by general diving technology; their ability to accomplish various missions have brought marine development into a new era (Hall 2006; Bonin-Font et al. 2017).

As human activity space gradually expands into the marine sector, underwater vehicles will have an important role in ocean exploration. Underwater vehicles development involves high technologies, such as mechanics, fluid mechanics, hydroacoustics, optics, electronic communication, navigation, automatic control, computer science, sensor technology, bionics, artificial intelligence, and many other contemporary achievements. The important application value of AUVs has received an increasing amount of attention from scientists and technologists in the civil and military fields. In the field of marine engineering, AUVs are employed for the structural inspection of dams, installation/disassembly of underwater bases, observation of underwater targets, and search and rescue; they also aid divers. In the field of marine scientific research, AUVs can be deployed to conduct data collection in a marine environment, investigate underwater shipwrecks, perform geological and geomorphological exploration of the seabed, and explore petroleum and other resources. In the military field, AUVs are used in mine countermeasures, target detection, intelligence gathering, surveillance and reconnaissance, environmental data collection, and anti-submarine warfare. To achieve environmental perception and autonomous navigation of underwater vehicles, a variety of techniques is required to collaborate on an AUV (Dagleish et al. 2007; Xu et al. 2007).

General System Structure of Underwater Vehicles

Marine scientists are among the first to capitalize on the use of underwater vehicles for environmental perception. Oceanographers, for instance,

started using unmanned underwater vehicles (UUVs) to study deep marine environments and the seafloor. However, although the majority of such early applications were devoted to monitoring marine habitats, nowadays there are a significant and increasing number of underwater vehicles that contribute to other environmental science domains.

With the increased selection of sensors now included in the AUV allowing the performance of underwater explorations, the system composition and structure of underwater vehicles have become much more complex, as shown in Fig. 1, and at the same time, the functions of the vehicles have become more powerful. The underwater 3D mapping now relies on acoustic multibeam or side-scan sonars to produce elevations maps (Hurtos et al. 2010; Pathak et al. 2010). This ability to accurately map underwater environments yields high added value to any survey, as such results convey immense information easily interpretable by humans.

Environmental Perception Technologies

Sonar Perception

Reliable, sonar-based perception is crucial if robots are to perform useful tasks in the ocean. Undersea sonar data, however, is not easy to interpret. The dominant approach for undersea sonar processing is based on “imaging.” Undersea sonars are often designed to create as large an aperture as possible, resulting in narrow beam patterns. These beams can then be steered, either mechanically or electronically, to produce a visual representation of the scene – an image. Most interpretation is either performed manually by human operators or automatically by image processing algorithms such as shadow detection. Common examples of imaging undersea acoustic sensors include side-scan sonars, forward-look sonars, and mechanically scanned sonars.

In most work in synthetic aperture sonar (SAS) the implicit goal is to produce an “image” of the scattered field (Rolt 1991). One of the key issues in a geometrical approach to sonar data interpretation is the correspondence problem. The goal is to associate measurements obtained from multiple

Environmental Perception for Underwater Vehicles, Fig. 1 The relationship of AUV autonomous control system structure. (Li et al. 2018)

vantage points with the same feature/object in a scene. Previous approaches have considered the correspondence problem in conjunction with the object classification and mapping problems (Moran et al. 1997). Freedman's method predicts that when a sonar pulse is an incident on a generally smooth but possibly faceted object, the returned waveform will be comprised of a discrete number of image pulses, which are time-delayed and attenuated replicas of the incident pulse. This simplified physical model of the sonar sensing process is based on the geometrical acoustics high-frequency approximation of acoustic scattering (Rikoski and Leonard 2003).

Optical Perception

Underwater environments with their particular phenomena (i.e., light attenuation, blurring, and low contrast) can be regarded as hostile places for optical surveying. Acquisitions have to be performed at close range, significantly limiting the area viewed in a single image, thus enormous amounts of data have to be collected and

processed to generate a wide-area view enabling the extraction of valuable information on a broader space scale. In scenarios with significant 3D structures, the aforementioned prerequisites cannot be met, resulting in obvious distortions. However, redundant information from multiple images can be used to provide visually rich 3D reconstructions of the underwater terrain. Furthermore, as the camera poses do not have to be orthogonal to the seafloor, images can convey more meaningful information regarding the global shape of the object, especially in the case of intricate structures (e.g., underwater hydrothermal vents), which are impossible to capture accurately using downward-looking cameras.

Hernandez et al. (2016) have presented an optical-based 3D reconstruction pipeline. Through a series of sequential modules, as shown in Fig. 2, the pipeline is able to reconstruct a 3D model based on the optical imagery acquired from an arbitrary number of cameras in various poses. Cameras do not have to be synchronized and can be freely repositioned between missions, based on the

Environmental Perception for Underwater Vehicles, Fig. 2 3D reconstruction pipeline. (Hernandez et al. 2016)

mission’s goals and the expectations of the terrain in the surveyed area. However, in order to obtain a metric-scaled reconstruction, the cameras have to be connected with the other sensors in the AUV or known measurements of the environment have to be introduced (Garcia et al. 2011). Each of the reconstruction steps results in a different representation of the reconstruction. While the preferable representation for visualization and dissemination is a textured triangle mesh, some applications may require solely dense or even a sparse point cloud of points describing the observed area. It is also worth noting that an important preprocessing step of color correction is required to reduce the image degradation effects of the water medium.

Laser Perception

Blue and green laser systems provide underwater target detection with a higher range, more precise positioning, and better imaging than traditional electromagnetic and acoustic detection. These systems are often utilized for underwater laser short-range target detection technology research. Underwater vehicles equipped with laser detectors can complement sonar detection technology obtain high-precision underwater images, enhance the

detection capability of underwater targets – especially underwater high-speed moving targets – and assist in completing various underwater exploration tasks (Zha and Zhang 2014).

When blue and green laser pulses are transmitted underwater, the beam energy attenuates due to the strong absorption and scattering of the seawater. The strong scattering effect causes the beam to diffuse in space, and the multipath effect of the photon leads to optical pulse broadening and transmission delay which altogether degrade the accuracy of underwater pulse laser ranging. At present, research on the underwater laser detection system mainly focuses on the transmission characteristics of light in seawater and the elimination of backscattering noise. Signal intensity, noise estimation, pulse distortion, and other factors are mainly studied, and the signal processing of the receiving circuit is simplified (Lee et al. 2013; Zotta et al. 2014).

Key Applications

Woock (2012) has discussed what type of features is suitable for sonar-based underwater navigation.

For evaluation, a simulation environment has been created (Fig. 3) which performs environment shape reconstruction based on side-scan sonar data while additionally utilizing vehicular inertial measurement data. A ray-tracing based forward model creates a synthetic sonar response for a given elevation map and vehicle pose. Then, a pose-aware inversion method estimates an elevation map of the surrounding environment. This map is the basis for navigation. Therefore, the characteristics of the reconstruction method need to be taken into account for the feature design as well as the fact that the surface will be sampled differently upon a re-visit (Woock 2012).

Environmental Perception for Underwater Vehicles, Fig. 3 The scheme of sonar perception method. (Woock 2012)

The TIETeK project is a joint Fraunhofer research project with the goal of showcasing technologies for deep-sea exploration and inspection tasks up to a depth of 6000 m. A prototype vehicle incorporating various Fraunhofer deep-sea technologies has been built and is shown in Fig. 4. The vehicle is of pressure-independent design and therefore features no pressure hull. With regard to sonar and data processing, the vehicle is equipped with two side-scan sonar sensors of switchable frequency (250 kHz, 500 kHz, 1 MHz), an Xsens IMU, a fiber-optic gyroscope, and a computing board (Woock 2012).

Hernandez et al. (2016) have presented a new end-to-end approach for autonomously mapping unknown underwater natural environments using AUV. They propose a framework composed of two main functional pipelines. The first provides the AUV with the capability for creating an acoustic map online, while simultaneously planning collision-free paths. Such functionality is essential for safe navigation in unknown and potentially dangerous areas, and to maintain a very short distance to the areas being imaged, as required by optical mapping underwater. Using the gathered image data, the second pipeline builds a photo-realistic 3D model, which can be used as base maps for environmental inspection and subsequent monitoring. In order to thoroughly validate the proposed approach, Hernandez et al. present the results obtained in a challenging real-

Environmental Perception for Underwater Vehicles, Fig. 4 The Fraunhofer prototype vehicle of the TIETeK project. (Woock 2012)

world natural scenario, in which the Sparus II AUV (Fig. 5) conducts several autonomous missions. The test scenario, containing an underwater canyon between two rocky formations, permitted the researchers to demonstrate the extent of the capabilities of the approach. By successfully navigating through the natural environment, the Sparus II AUV is able to acquire data subsequently used in the reconstruction of a complex textured 3D model of the area.

Korotkova and Yao (2020) have implemented a novel matrix method based on the extended Huygens-Fresnel integral for the analysis of optical beam propagation in the bi-static and mono-static LIDAR (Light Detection and Ranging) systems operating in the presence of underwater turbulence, as show in Fig. 6. By applying three transformations: for the beam passage from source to target, for its interaction with the target,

and for its propagation from target to the receiver, sequentially, they illustrate how the second-order moments of the beam can be predicted and compared at the source plane, just before the target, just after the target, and at the collecting lens of the receiving system. They have also carried out a very detailed numerical analysis of the beam evolution in a bi-static LIDAR system, using, without loss of generality, a linearly polarized and fairly coherent source. The results indicate that the underwater optical turbulence degrades the spectral density and the degree of coherence as follows: the lower value of the average temperature, a larger value of the temperature dissipation rate, or a smaller value of kinetic energy dissipation leads to more beam broadening and lower coherence. They have also illustrated that other parameters of turbulence affect the beam in a very complex manner.

Eutrophication

Haiyan Jin, Dewang Li and Zhenming Zheng
Key Laboratory of Marine Ecosystem Dynamics,
Second Institute of Oceanography, Ministry of
Natural Resources, Hangzhou, China

Synonyms

Eutrophicated water; Eutrophication control;
Harmful ecological effects; High nutrients

Definition

Eutrophication is the process of increased anthropogenic nutrient inputs to lakes, estuaries, and other aquatic systems over the natural supply and the subsequent excessive biological production of organic matters. Nutrient fertilization in

aquatic environments may result in a series of harmful ecological effects including the development of hypoxia ($[O_2] < 62.5 \mu M$), acidification, and die-off of fishes and benthic organisms in waters (Fig. 1).

Introduction

Eutrophication, the process of changing water system from nutrient-poor to nutrient-rich, negatively influences water quality. It profoundly increases the biomass of undesirable species. Even, it increases the occurrence of harmful algal blooms in the lakes, estuaries, and coastal regions (Zhou et al. 2008; Jin et al. 2010; Jiang et al. 2014; Wang et al. 2017; Chen et al. 2020).

Algae use sunlight, water, carbon dioxide, as well as nutrients to build organic matter for their own growth, development, reproduction, and other life activities. In considerable aquatic environments, nitrogen and phosphorus limit

Eutrophication, Fig. 1 Schematic view of eutrophication (OSPAR 2010, https://qsr2010.ospar.org/en/ch04_01.html)

phytoplankton growth. However, because of human activity, a large amount of domestic sewages and industrial wastewaters, which are rich in nutrients such as nitrate and phosphate, are discharged into lakes, estuaries and nearshore waters. Such enormous nutrient input even trigger explosive growth of phytoplankton in marginal seas (Wang et al. 2017). In a favorable water condition, biomass will accumulated due to intense algae bloom which blocks sunlight into water. Subsequently, oxygen dissolved in water are consumed significantly by decomposition of organic matters.

Eutrophication

Nutrient Source for Eutrophication

The nutrients needed by phytoplankton in seawater mainly include nitrogen, phosphorus, silicon, carbon, trace elements, and various vitamins. In general, the limiting factors for the phytoplankton growth are nitrogen and phosphorus, rather than silicon and carbon in seawater. Silicon limitation and iron limitation are mainly reported in open oceans. The main sources of nutrients in coastal waters include:

1. Terrestrial runoff. Terrestrial runoff mainly includes rivers, domestic sewages, and industrial and agricultural wastewater. Riverine nutrients are usually the most important nutrient source in the estuary and coastal waters. The extreme high nutrient concentrations in runoff contribute to the eutrophication of coastal waters and trigger intense algae bloom (Turner and Rabalais 1994; Grelowski et al. 2000; Wu et al. 2020).
2. Atmospheric nutrient deposition. Atmospheric input is an important source of nitrogen in coastal waters. The combustion of fossil fuel and automobile exhaust leave nitrogen oxides in the air, which enter aquatic environment by dry and wet deposition. By comparison, atmospheric deposition of phosphorus is much smaller than that of nitrogen (Beddig et al. 1997; Rendell et al. 2017).
3. Aquaculture wastewater. Aquaculture wastewater contain large amount of unused bait and fecal pellets. Degradation of the organic matters by bacterial release inorganic nutrients into waters, which also contribute to the eutrophication process

Ecological Effect

Algal Blooms and Red Tide

The eutrophication of lakes, estuaries, and coastal waters favors the growth of algae or aquatic plants. The floating plants may cover the surface waters or even filled the water column in shallow waters. The biomass accumulation of algae or aquatic plants in waters decreases transparency of water body, which blocks the penetration of sunlight. The eutrophication in coastal waters may even trigger red tide, during which algal blooms are so intense that they even discolor the coastal waters. Under a worse condition, harmful algae will release toxin that will kill fish, shellfish, marine mammal, and birds and threaten the health of human being.

Hypoxia and Subsurface Acidification

Algal blooms in coastal waters produce enormous organic matters during the exponential growth phase. As the nutrients are depleted, and sunlight is blocked by surface algae, phytoplankton growth slows. The decomposition of organic matter exceeds the production of organic matter eventually. Thus, the oxygen level will decrease continuously. In the river estuary and marginal seas, eutrophication results in intense phytoplankton blooms in upper layer, and the subsequent setting and decomposition of fresh organic carbon contribute to severe hypoxia and acidification in the bottom water (Cai et al. 2011). The extreme low oxygen level, or even the generation of H_2S , results in the death of fishes and benthic organisms. Thus, the hypoxic waters are also called “dead zone.”

Simplification of Food Web Structure

The process of eutrophication reduced the number of species and increased the abundance of mesoeutrophic to hypereutrophic species (Van

Dam and Mertens 1993), which will cause changes in species relationship in the community, simplified food web structure. A shift in primary producers from eelgrass to macroalgae in response to increased nutrient loading is found (Deegan et al. 2002). It altered the habitat, physicochemical structure, and food webs. The nitrogen decrease lowers the density and biomass of eelgrass. However, it promotes a record-increase of algal biomass. Serious eutrophication can also lead to the loss of important marine habitats such as seagrass beds and coral reefs.

Evaluation of Eutrophication Level

$$E = c(\text{COD}) \times c(\text{DIN}) \times c(\text{DIP}) \times 10^6 / 4500*$$

E is the nutrient index (First Institute of Oceanography Ministry of Natural Resources 2008).

$E \geq 1$ indicates the water area has exhibited the characteristics of eutrophication.

$c(\text{COD})$ is the concentration of chemical oxygen consumption, mg/dm^3 .

$c(\text{DIN})$ is the concentration of dissolved inorganic nitrogen, mg/dm^3 .

$c(\text{DIP})$ is the concentration of dissolved inorganic phosphorus, mg/dm^3 .

4500 is the product of single eutrophication threshold values of COD, DIN, and DIP for specific oceans or lakes. These three thresholds are distinct for various aquatic environments. Threshold ranges of COD $1 \sim 3 \text{ mg}/\text{dm}^3$, DIN $0.2 \sim 0.3 \text{ mg}/\text{dm}^3$, DIP $0.01 \sim 0.02 \text{ mg}/\text{dm}^3$ were suggested and recommended.

Eutrophication Control

Eutrophication is worsen in lakes, estuaries, and coastal regions all around the world, especially in the context of global change. Nutrient inputs to aquatic system are mainly from human activities (agriculture fertilization, sewage discharge, aquaculture, etc.). Thus, the effective treatment of eutrophication is “prevention and protection” strategy in lots of countries, including ecosystem-based management, reducing the use of nitrogen fertilization, implementing pollutant emission control, developing watershed protection, and increasing water self-purification capacity.

Biological control is one of the common methods to control eutrophication. Some aquatic macrophytes, such as *Alternanthera philoxeroides*, which improves the transparency of eutrophic lake water, are capable of purifying eutrophic lake water (Wang et al. 1999). *Hydrodictyon reticulatum* was reported to actively remove 67.3% nitrogen and phosphorus in 6 days under different environmental conditions (Liu et al. 2004). Some phytoplanktivorous fish can be utilized for weed management and counteracting eutrophication (Opuszynski et al. 1995). Several microorganisms are reported to be efficient for scavenging phosphates from sewage sludge (Lawson and Tonhazy 1980; Florentz and Hartemann 1984).

Excessive Accelerations

Min Gu, Jiang Lu, Shuxia Bu, Jilong Chu,
Ke Zeng and Tianhua Wang
China Ship Scientific Research Center (CSSRC),
Wuxi, China

Definition

When a ship is rolling, objects in higher locations travel longer distances. A period of roll motions is the same for all the locations onboard the ship. To cover a longer distance during the same time, the linear velocity must be larger. As the velocity changes its direction every half a period, larger linear velocity leads to larger linear acceleration. Large linear acceleration means larger inertial force, see Fig. 1 (SDC 3/WP.5/Annex 7 2016).

Inertial forces acting in the horizontal plane are more dangerous for a human than vertical inertial forces. The vertical inertia forces cause brief overloading, while horizontal inertia forces cause humans to lose balance, fall, or even be thrown against walls, bulkheads, or other structures. Large acceleration is mostly caused by roll motions, so they have predominantly lateral direction.

If GM value is large, the period of roll motion is smaller. Thus, for the same roll angle changes of linear velocity occur faster, so acceleration is larger (SDC 3/WP.5/Annex 7 2016).

Typical Excessive Accelerations Accident

In the years 2008/2009 the world economic crisis caused a reduction in the number of transported TEU, due to a significant decrease in transported goods. Consequently, a great number of container vessels had been laid up or were forced to operate with a small amount of cargo on board. In this loading condition container vessels have very high stability. In many cases, their vertical center of gravity is even located below the lightship condition's coordinate. This is due to large amounts of ballast water in wing and double

Excessive Accelerations, Fig. 1 Scenario of stability failure related to excessive accelerations (SDC 3/WP.5/Annex 7 2016)

bottom tanks as well as no or only a small amount of cargo located at cargo hold bottom. A high amount of ballast water is needed to obtain an adequate hull and propeller immersion as well as a limitation of the longitudinal bending moments within the hull structure. In the typical loading conditions with higher amounts of cargo, less ballast water is needed, and the stability is lower. Under the described circumstances, several accidents have happened to container vessels during the last years. Accidents caused not only severe damages on ships but also heavily injured and even killed crew members. They have been thrown through the bridge due to high transversal acceleration caused by the heavy roll motions of the ship. This highlights that modern container ship designs face some problems concerning insufficient seakeeping behavior (SLF54/INF.7 2011).

The accident of the CMS Chicago Express happened on September 24th, 2008, during heavy weather in the South China Sea near Hong Kong. The maximum rolling angle was about 35° , and the maximum transversal acceleration on the bridge exceeded 1.0 g. One crew member was killed, one heavily injured, and several slightly injured. There were no noticeable damages to the vessel's hull (SLF54/INF.7 2011).

The accident of a 2468 TEU containership happened on September 15th, 2009, during heavy weather in the South China Sea near Hong Kong. The maximum rolling angle was about 30° . The maximum transversal acceleration on the bridge exceeded 1.2 g. One crew member

was killed. Heavy damages to the vessel's hull occurred (SLF54/INF.7 2011).

The accident of a 2500TEU containership happened on October 16th, 2009, during heavy weather in the North Sea near Borkum. The maximum rolling angle was about 30° . The maximum transversal acceleration on the bridge exceeded 1.0 g. One crew member was heavily injured. No damages to the vessel's hull occurred (SLF54/INF.7 2011).

Model Test for Excessive Acceleration

The existing accidents show that the excessive acceleration generally occurs in the ballast condition. The larger GM value and the smaller roll damping caused by a stall in waves will lead to the excessive lateral acceleration at the higher position of the hull under such loading conditions. In case of excessive acceleration, the rolling amplitude of the accident ship can exceed 30° . Due to excessive stability and short period, the maximum lateral acceleration could exceed 1.0 g. The speed of the hull was quite low when the accident occurred. It is reported that when the two accidents of Chicago express and Guayas occurred, the navigation speed was particularly low, only about 2–4 knots.

From the above analysis, it can be seen that under ballast or close to ballast and low speed, excessive acceleration is more likely to occur, which will be accompanied by large roll amplitude. Therefore, the beam wave and zero speed are

usually selected for the research of excessive acceleration. At this time, resonance rolling is easy to occur, which is easy to cause excessive acceleration.

Here is an example of a model test of excessive acceleration. One containership is selected, and the principal particulars are given in Table 1. Model test photos are shown in Fig. 2. Excessive acceleration model test was carried out in the seakeeping basin of China Ship Scientific Research Center. The model test is restrained by four springs.

The lateral accelerations of the three measuring points are measured by the acceleration sensor, and the coordinates of the measuring points are listed in Table 2. The layout of measuring points on the model are respectively at the port side of the center of gravity (P1), the starboard side of the cab (P2), and the starboard side of station 0 at the stern of the model (P3), as shown in Table 2.

Firstly, the model test of the free roll decay curve is carried out, and then the model test is carried out in regular and irregular beam waves at

zero speed. Eleven wave conditions in regular beam waves are carried out, with wavelength/ship length = 0.2, 0.3, 0.4, 0.6, 0.8, 1.0, 1.2, 1.4, 1.6, 1.8, and 2.0, respectively, and the wave steepness is fixed at 0.03. Irregular wave conditions are shown in Table 3, and ITTC 2-parameter spectrum is used for simulation.

Key Numerical Method for Excessive Acceleration

It is widely accepted that the degrees of freedom (DOF) of a rigid body in a three-dimensional space is six but can be reduced if constraints are added. The 3DOF coupled mathematical model (heave-roll-pitch) and 4DOF coupled mathematical model (sway-heave-roll-pitch) are usually used for direct stability assessment of excessive acceleration. In the simulation, the Froude-Krylov and hydrostatics forces were calculated by integrating the incident wave pressure around the instantaneous wetted hull surface. Radiation and diffraction forces were calculated on the basis of the initial averaged submerged hull. Roll damping coefficients were obtained from the free roll decay motions.

The schematic diagram of lateral acceleration in the calculation is shown in Fig. 3, and the formula is:

Excessive Accelerations, Table 1 Principal particulars of the sample containership

Items	Value	Items	Value
Length: (L_{pp})	251.88 m	Displ. (W)	27543.05ton
Breadth (B)	32.2 m	Draft (T)	6.225 m
Metacentric height (GM)	6.132 m	Natural roll period (T)	11.173 s

Excessive Accelerations, Table 2 Definition for three measuring points

No.	Coordinate		
	X(m)	Y (m)	Z (m)
P1	112.22	14.75	19.87
P2	54.35	−15.53	45
P3	0	−14.18	19.87

Excessive Accelerations, Fig. 2 Model test photo of the sample containership

Excessive Accelerations, Table 3 Wave conditions in irregular waves

No.		$H_{1/3}$ (m)	T_z (s)
1	ITTC 2-parameter spectrum	5.5	7.5
2			8.5
3		6.5	8.5
4			10.5

$$\begin{aligned} a_l &= (g - a_v) \sin(\varphi) + a_H \cos(\varphi) \\ a_n &= -(g - a_v) \cos(\varphi) + a_H \sin(\varphi) \end{aligned} \tag{1}$$

where, a_l and a_n are acceleration components along the deck direction and normal to the

deck, respectively. a_v and a_H are vertical and horizontal components, respectively.

The Effect of Degree of Freedom on Excessive Acceleration

The effect of the degree of freedom on excessive acceleration is compared by taking the sample containership as an example. Firstly, the roll moment of inertia of the 4DOF coupled mathematical model is adjusted by using the free roll decay curve measured in the model test. The calculated free roll decay (Ixx-Tune) after adjustment is consistent with the free roll decay curve obtained by the test, as shown in Fig. 4.

Figure 5 displays roll amplitudes under different wave conditions. Figures 6, 7, and 8 shows the lateral acceleration of three measuring positions in regular waves and irregular waves. The results show that the calculation results of the 4DOF

Excessive Accelerations, Fig. 3 Schematic for the calculation of lateral acceleration

Excessive Accelerations, Fig. 4 Comparison of calculated free roll decay curves and experimental free roll decay curves

Excessive Accelerations, Fig. 5 Comparison of roll amplitudes in regular and irregular wave

Excessive Accelerations, Fig. 6 Comparison of maximum lateral acceleration at position p1

Excessive Accelerations, Fig. 7 Comparison of maximum lateral acceleration at position p2

Excessive Accelerations, Fig. 8 Comparison of maximum lateral acceleration at position p3

model agree well with the model test results, but the calculation results are slightly smaller than those of model test in several conditions. The calculation results of the 3DOF model are larger

than those of the model test results in the whole frequency range. The comparison results show that the roll moment of inertia has an influence on the accuracy of the 4DOF mathematical model.

The Effect of Calculation Position on Excessive Acceleration

The results of lateral acceleration are related to the ship roll amplitude and the position of the calculation point. The effects of the height of calculation position are studied by taking P2 as an example. Four calculation heights (H1 = 19.87 m, H2 = 30.73 m, H3 = 45.0 m, and H4 = 60.73 m) are chosen. From the calculation results shown in Fig. 9 (left), it can be observed that the lateral acceleration increases with the increase of the calculation height. Then draw the maximum lateral acceleration (resonance roll) corresponding to each height into Fig. 9 (right). It can be seen that the lateral acceleration basically changes linearly with the increase of height.

The different longitudinal positions and transverse positions are selected to calculate the lateral

acceleration at the roll resonance. The calculation results are shown in Fig. 10. Figure 10 (left) shows the change of lateral acceleration with longitudinal position and Fig. 10 (right) shows the change of lateral acceleration with transverse position. It can be seen that the change of longitudinal and transverse position has little effect on the lateral acceleration.

Simplified Method for Excessive Acceleration

The acceleration at any position of the hull can be calculated by the simplified formula (1), as proposed by IMO second generation intact ship stability criteria (IMO SDC 3/WP. 5 Annex 2)

$$a_{y_sim} = k_L (g \sin(\varphi_a) + h\omega_j^2 \varphi_a) \quad (2)$$

Excessive Accelerations, Fig. 9 Lateral accelerations along with the height of calculation position

Excessive Accelerations, Fig. 10 Lateral accelerations along with longitudinal and horizontal positions

The reliability of this formula is verified by the comparisons between different methods and model tests results by taking the sample container-ship as an example.

The results are shown in Figs. 11, 12, and 13 in which the Exp represents the lateral acceleration measured by the model tests, Exp-sim represents

roll amplitude in formula (1) obtained from model tests, 3DOF-sim represents roll amplitude in formula (1) obtained from 3DOF coupled mathematical model tests, and 4DOF-sim represents roll amplitude in formula (1) obtained from 4DOF coupled mathematical model tests. We can see that the calculated results based on the simplified

Excessive Accelerations, Fig. 11 Comparisons of lateral acceleration by simplified method at position p1

Excessive Accelerations, Fig. 12 Comparisons of lateral acceleration by simplified method at position p2

Excessive Accelerations, Fig. 13 Comparisons of lateral acceleration by simplified method at position p3

formula for excessive acceleration are also in good agreement with the model test results, on the basis of accurate calculation of roll angle.

Definition

Testing is a reliable approach to investigate the performance of a marine and offshore renewable energy system. The general concept of “testing” includes field testing and lab testing. Field testing is typically conducted in the oceans and employs a full-scale test model although the test model may be scaled occasionally. Comparatively, lab testing is usually model-scaled and carried out in experimental environment (wind tunnel, ocean basin, etc.) so that a scaling law must be developed and applied. When we refer to testing, it usually indicates the lab testing. The testing approach is commonly used when the physical response of the renewable energy system is too complicated to analyze numerically. A testing campaign may also be launched to validate numerical model.

Application of Testing in Renewable Energy Research

Test Facility

Unlike field test where wind, wave, and tidal current are available from the nature, lab test requires us to build up the experimental environment and generate the environmental conditions manually. Typical test facilities to build up the experimental environment are wave flume, wind tunnel, and ocean basin.

Wave Flume

Wave flume, or wave tank, is a laboratory setup used for the generation of surface ocean waves. Typical wave flume is a slender box filled with water, leaving open on top (see Fig. 1). Wave generation device is located at one end and the other end usually installs a wave-absorbing beach to eliminate the wave reflection. Wave flume is usually used in the model test of wave energy converter. Due to the geometry limit of wave flume in width, it is only applicable to the test of a single energy device. Nowadays, increasing attention is paid to the energy device array so that alternative facilities must be used, e.g., the ocean basin. Also, the wave in the tank only propagates along one single direction, meaning that only long-crested waves can be generated.

Experimental Investigation of Offshore Renewable Energy, Fig. 1 Wave flume at Kelvin Hydrodynamic Laboratory, UK (Kelvin Hydrodynamic Laboratory 2018)

Experimental Investigation of Offshore Renewable Energy, Fig. 2 NASA wind tunnel with the model of an aircraft (NASA 2017)

They can also be used to test tidal turbines, which are actually towed by a moving carriage to mimic the current effect.

Wind Tunnel

Wind tunnel is a tool used in aerodynamic research to examine the dynamic behavior of a solid object (a blade model, an aircraft model, etc.) in airflow. Fig. 2 illustrates the NASA wind tunnel. Wind tunnel is very similar to wave flume, consisting of a fan system to generate incoming flow at one end, a tubular passage and

flow-dissipating system at the other end. For decades, wind tunnel is mostly applied in the field of aerospace, and it is until the proposal of offshore wind turbine that it is introduced to the realm of offshore and marine technology. Nowadays, it is mainly used to measure the aerodynamic coefficients of a specific airfoil adopted by the offshore wind turbine. Cavitation tunnel can be seen as another kind of wind tunnel. In a cavitation tunnel, the fluid is water. Cavitation tunnel is mostly used in the model test of tidal turbine.

Ocean Basin

Ocean basin is probably the most representative facility in offshore and marine technology. It is basically a wave tank with width and length of comparable magnitude but distinguished by its wave generation ability. Ocean basin is able to generate multidirectional waves, multidirectional currents, and interactions of them. Wind generation system may also be installed to model offshore wind. Current generation system is frequently equipped to simulate tidal current. Fig. 3 sketches the ocean basin at Shanghai Jiao Tong University. Ocean basin can be used for test of various energy devices, ranging from offshore wind turbine, wave energy converter, wind turbine, or combination of them.

Scaling Law

The energy device in a test is typically scaled down from the prototype, even in a field test. It is straightforward to scale the device according to geometry similitude. For example, the prototype is a box with dimension $10\text{ m} \times 10\text{ m} \times 10\text{ m}$ and the model can be scaled down to $1\text{ m} \times 1\text{ m} \times 1\text{ m}$ with a scaling ratio of 1:10. Then, we let the prototype moves with a speed of 1 m/s. What the scaled speed in the test should be? 1/10 m/s, is it right? In practice, the scaling algorithm we apply in a model test could be far more complicated. In addition to geometry similitude, we must also maintain dynamic similitude. Depending on the

dominating load in the test, we introduce Reynolds number (Re), Froude number (Fr), and Euler number (Eu) to fulfill such goal.

$$Re = \frac{\rho u L}{\nu}$$

$$Fr = \frac{u}{\sqrt{gL}}$$

$$Eu = \frac{2\Delta p}{\rho u^2}$$

where u is the speed, L is a characteristic length dimension, ρ is the fluid density, ν is the dynamic viscosity of the fluid, g is the acceleration of gravity, and Δp is the gradient of fluid pressure.

Reynolds Number

Reynolds number represents the ratio of inertial forces to viscous forces within a fluid (water or air). In low number case, sheet-like flow dominates. Otherwise, turbulence caused by the difference in the fluid's direction and speed is significant. If viscous force dominates the physical process, we tend to maintain Reynolds number. It is the case in the model test of wind turbine and tidal turbine.

Froude Number

Froude number represents the ratio of inertial forces to gravity. Froude number is maintained

Experimental Investigation of Offshore Renewable Energy,

Fig. 3 Deepwater offshore basin at Shanghai Jiao Tong University, China (State Key Laboratory of Ocean Engineering 2018)

when the inertial fluid forces play an important role. More specifically, we maintain Froude number if the wave force is the primary excitation load. Model test of wave energy converter adopts the Froude number similitude. Similarly, model test for hydrodynamics of floating wind turbines follows the Froude scaling law.

Euler Number

Euler number describes the ratio of inertial forces to pressure gradient. Euler scaling law is mainly used in the experimental investigation of cavitation and noise of tidal turbine so that it is sometimes named as the cavitation number. Euler scaling law is not often used in the model test is offshore renewable energy system.

Test Campaign

To deepen our understanding on the dynamic response of offshore and marine renewable energy system as well as to validate a suite of benchmark models and simulations, several test campaigns (both field test and lab test) have been launched.

Offshore Wind Turbine

In 2009, Equinor (formerly Statoil) launched the Hywind demo project (see Fig. 4), which is the first full-scale offshore floating wind turbine prototype in the world (Equinor 2017). The 2.3 MW Hywind concept (see Fig. 5), supported by a spar-type floating platform, is located 12 km off Norway's south-west coastline. The floating system is anchored to the seafloor with three mooring lines. Just 1 year later, Principle Power set up the field test of a full-scale floating wind turbine concept – WindFloat (Principle Power 2015). A 2 MW wind turbine is mounted on a semi-submersible floating platform, which is installed 5 km off the Portuguese coast. In 2017, the world's first floating wind farm – Hywind Scotland was opened about 30 km off the coast of Scotland. The Hywind Scotland earns experiences and technology from the Hywind demo project to provide power to the national grid. Since the above field tests are managed by industrial sector, the measured data are hardly open to the public.

In addition to field test, lab tests have been insensitively carried out in the academic

Experimental Investigation of Offshore Renewable Energy, Fig. 4 Hywind demo concept (Equinor 2017)

Experimental Investigation of Offshore Renewable Energy, Fig. 5 WindFloat concept (Principle Power 2015)

community. The OC4-DeepCwind test campaign is launched under the collaboration of a couple of participants. The lab test was performed at Maritime Research Institute Netherlands to assess the unique behavior of various platform concepts for floating wind turbine. This test campaign was primarily set up to generate benchmark experimental data to verify fully coupled tools for offshore floating turbine. The data recorded in the test are publicly available. In lab test, we have to focus on the major factors and ignore the minor factors. In most cases, we focus on wind load and wave load whereas structural dynamics can be somewhat simplified. It is ideal to scale aerodynamic and hydrodynamic loads accurately at the same time. Unfortunately, we cannot maintain Reynolds number and Froude number simultaneously. Please recall the question at the beginning. If we are to maintain Reynolds number, the scaled speed of the prototype should be 10 m/s. The speed is scaled down to 0.32 m/s if Froude number is maintained. What we typically do is maintaining Froude number to scale wave load properly and develop alternative approaches to acquire the desired wind load. For example, Martin et al. (2014) corrected Reynolds number effect by roughening the leading edge of the blades. Other research even abandoned the blades and used a disc to produce the wind load.

Wave Energy Converter

Compared with offshore wind turbine, wave energy technology appears to be less popular, but a large number of field tests have been conducted so far. The Wave Dragon concept (Wave Dragon ApS 2013), the world's first offshore grid-connected wave energy device, was first tested in 2004. This test unit supplied electricity to the grid for more than 20,000 hours. The Pelamis project (European Marine Energy Centre 2018) was launched by Pelamis Wave Power in 2014, which successfully provided power to the national grid of Scotland. The Pelamis is the world's first offshore wave power converter to successfully generate electricity into a national grid. However, most of the field tests did not last for a long duration, typically less than 1 year. Most recently, wave energy converter lab test begins to put its focus on array effect. When a set of wave energy converters are displaced together to constitute an array, the hydrodynamic interaction between them will have a significant influence on power production. Stratigaki et al. (2014) measured the dynamic response of wave energy converter for a range of geometric layout configurations at a water basin to provide data for understanding array hydrodynamic interactions. Fig. 6 gives a sketch of the wave energy converter array. The

Experimental Investigation of Offshore Renewable Energy, Fig. 6 Model test of wave energy converter array (Stratigaki et al. 2014)

recorded data may also be used to validate array interaction numerical models.

Tidal Turbine

Tidal turbine is very similar to a land-based wind turbine. Tidal turbine test is typically conducted in a wave tank or a cavitation tunnel. Since most industrial tidal turbine products are fixed to the seafloor, tidal turbine model test mostly focus on thrust force and power capture. Batten et al. (2007) measured steady power and thrust coefficients of a 1/20th scale tidal turbine. Recently, the research community shows great interest in the tidal turbine performance under wave-current interaction. In this circumstance, the model test must be performed in a wave flume or an ocean basin. Relevant work on this specific field was reported by Luznik et al. (2013).

Hybrid System

Hybrid energy system is proposed as a technical solution to the efficient exploitation of offshore and

marine energy recourses. The hybrid concept is mainly proposed for two objectives: (1) increase the overall power production; (2) enhance the dynamic performance (motion, structural load, etc.) via the combination of different offshore renewable energy devices. Until now, no field test is available although some lab test measurements have been reported. Wan et al. (2016) conducted a series of tests to assess the dynamic response of the STC, a combination of a spar-type floating wind turbine and a heaving-body wave energy converter. The SFC concept integrates a semisubmersible-type floating wind turbine and a flap-type wave energy converter. Michailides et al. (2016) experimentally measured its dynamic performance in the ocean basin in Ecole Centrale Nantes.

Experimental Techniques for VLFS

Haining Lyu

School of Naval Architecture, Ocean and Civil Engineering, Shanghai Jiao Tong University, Shanghai, China

Definition

Model test plays a very important role in the research process of very large floating structures (VLFS). Many challenges on the experimental techniques are encountered due to the large dimensions compared with the conventional marine structures. Firstly, due to the large horizontal dimensions of the VLFS, ocean environment has great changes in the area over the structure. There are a lot of problems unsolved in the experimental research of nonuniform ocean environment. Secondly, because of the extremely large dimension of VLFS, a large-scale ratio has to be adopted in the model tests, which could induce an obvious scale effect and thus make a great difference on the test results. In addition, in order to simulate and measure the hydroelastic properties of the VLFS accurately, the test design and measuring system are more complicated than that for conventional marine structures, which can be regarded as rigid bodies.

Scientific Fundamentals

Historical Development

Model Experiment on Hydroelasticity of VLFS

With the development of theoretical researches, experimental research on VLFS is also developing very fast. Many countries, such as Japan (VLFS '96), the USA (Ertekin and Riggs 1991, 1999), and Norway (Faltinsen 1996) among others, have paid much attention to the experimental research on VLFS, and they have made great progress.

Yago and Endo (1996a, b) carried out a model test in the basin of Ship Research Institute in Japan to study the hydroelastic behavior of VLFS. A box-typed model, which consists of two layers, is used. One layer is an aluminum alloyed honeycomb plate and the other is a polyethylene foam plastic plate. The two layers are agglutinated together. The model's dimension is $L \times B \times D \times d = 9.75 \text{ m} \times 1.95 \text{ m} \times 5.45 \text{ cm} \times 1.67 \text{ cm}$, and the scale ratio is 1:30.77. Where L is the model length, B the width, D the depth, and d the draught. The basin is 40 m long and 27.5 m wide. Four wave incidence angles are adopted: 0° , 30° , 60° , and 90° . In the model test, the wave period changes from 0.8 s to 2.5 s with four different wave heights: 1 cm, 2 cm, 6 cm, and 7 cm, respectively.

Ohmatsu and Namba (1996) also carried out hydroelastic, forced and free oscillation tests on a box-typed VLFS. The model's dimension is $L \times B \times D \times d = 50 \text{ m} \times 5 \text{ m} \times 4.4 \text{ cm} \times 1.0 \text{ cm}$, with a scale ratio of 1:100. It is made up with two aluminum plates with 1 mm in thickness. Polyethylene foam with 2 mm in thickness is filled in between the two aluminum plates to provide the rigidity needed. Below the plate, polyethylene foam with 4 cm in thickness is also agglutinated. The water basin is 140 m long and 7.5 m wide with water depth 0.45 m and 3.0 m, respectively, corresponding to the full scale of 45 m and 300 m. The purpose of the model tests is to observe and measure the hydroelastic responses of VLFS and determine its natural frequency, viscous damping coefficient, and the wave drift forces.

Shiraishi et al. (1996) (in VLFS '96) carried out a model test using six models with different widths, masses, and bending rigidities in a $19.0 \text{ m} \times 10.0 \text{ m}$ water basin. By measuring the motions and deformations, the hydroelastic performances of a box-typed VLFS are studied. It is shown that models with small bending rigidities have larger vertical displacement than those with greater bending rigidities, and all of these six models have large longitudinal displacement in waves.

Shin et al. (1999) carried out a model test, taking the model of the Technological Research Association of Mega-Float as the prototype. The dimension of the model is $L \times B \times D \times d = 7$

$\text{m} \times 1.4 \text{ m} \times 4.667 \text{ cm} \times 1.167 \text{ cm}$, and the scale ratio is 1:42.8. In the test, water depth is 18.7 cm and 250 cm, respectively, corresponding to the full scale of 8 m and 107 m. The model is made of foam plastic with alloyed frame. The foam is composed by many cells. Between every two adjacent cells there is a 3 mm wide space to avoid the influence of foam material on model's rigidity. The test results indicate that with the increase of incident wave length, the amplitude of VLFS deformation also increases. And the amplitude of the responses in shallow water is relatively smaller than that in infinite water depth. It also seems that the water depth has significant effect on the structure responses of VLFS in waves.

In 1999, Kagemoto et al. carried out a model test on hydroelastic response of VLFS (VLFS '99). The prototype is 5 km long, 1 km wide, and its depth is 5 m. The model is 3 m in length, 1 m in width, and 0.03 m in depth. In addition, the wave generator is able to generate waves with only 1 mm wave height and 10 Hz in frequency. And with optical technology and Moire method, the water surface and vertical displacements could be measured continuously during the model test.

A Mobile Offshore Base (MOB) model test has been carried out in Mc Dermott's in the US Naval Surface Warfare Center by Wu and Mills (1996). The model scale is 1:59. In the test, the model is connected by one, two, and five modules, respectively. The motions of the model, connector loads, and the mean drift forces in operational condition are measured. Results of the experiment are compared with that of calculations. According to the comparison, it shows good agreement while the number of modules is small, but with the increase of module number, the difference becomes increasingly great.

Model Experiment on Hydroelasticity of VLFS in Nonuniform Ocean Environment

Because of the large horizontal dimensions of the VLFS, ocean environment have great changes in the area over the structure. Therefore, uniform wave spectrum, which is based on the hypothesis of ergodicity and stationary stochastic process in both space and time, is not applicable here.

Instead, a new nonuniform wave spectrum varying with location needs to be established (Cui et al. 2001). However, most of the present researches on hydroelasticity of VLFS are based on the hypothesis of uniform ocean environment. Therefore, experimental research of VLFS in non-uniform ocean environment is quite essential.

There are a lot of problems unsolved in the experimental research of nonuniform ocean environment. First of all, because of the extremely large dimension of VLFS, and the topography variation of ocean bottom needed to be simulated in model basin, large-scale ratio has to be adopted in the model tests. Thus, the scale effect may have great influence on the model test results. Besides, there are few model tests on nonuniform ocean environment reported publicly. To describe the nonuniform ocean environment and its influence on motion and deformation of VLFS properly, it may be necessary to put forward a method to analyze and express the model test results.

Model tests of VLFS in nonuniform ocean environment have been performed in the model basin of State Key Laboratory of Ocean Engineering, SJTU (Lu et al. 2004). The VLFS model in these tests is box-typed. Its dimension is $L \times B \times D \times d = 10 \text{ m} \times 0.6 \text{ m} \times 3 \text{ cm} \times 1 \text{ cm}$, and the scale ratio is 1:100. The water depth changes between 0.2 m ~ 0.4 m. The model is made up with two layers. The upper layer is an aluminum plate 2.5 mm in thickness, while the lower one is foam plastic plate 27.5 mm in thickness. The two layers provide the required bending rigidity and buoyancy, respectively.

In the experiment, nonuniform ocean environment is simulated by setting a shoal model on the bottom of the basin. Altogether there are three shoal models with different shapes and dimensions used in the model tests. Two of them are basically 2-D shoals with different dimensions, and the third one is a 3-D shoal model. The 2-D shoal is a column with an elliptic section, while the 3-D one is a part of an ellipsoid.

The model test results show that the varying depth bottom of the ocean has great influence on the deformation of VLFS in shallow water. Compared with that of uniform ocean environment, VLFS has larger vertical displacement at the

location above the shoal. Moreover, the longer wave period, the smaller water depth, and larger shoals on the bottom have greater effect on VLFS.

Mooring System Experiment of VLFS

In exploitation of ocean space resources, VLFS are commonly moored to an offshore location for a long period over 100 years. Consequently, its mooring system has to face many problems. During the design of VLFS mooring system, the integrate effect of wind, wave, and current should be considered carefully.

The involved problems mainly include the influence of hydrodynamic forces, external forces, etc. With large horizontal dimension and relatively small draft, the horizontal motions of VLFS are quite different from ordinary floating structures. Since breakwaters are often set around VLFS for near-shore applications, the shape and propagation of waves are altered. And because of the asymmetry of VLFS superstructure, external forces acting on VLFS are also asymmetrical. These forces and the effect of wind and current also increase the difficulty of the mooring system design (Kinji et al. 1996).

The purpose of mooring system experiment is to study the forces on it. Ministry of Communication in Japan carried out a model test (Kato et al. 1996) to study the mooring system's reliability in the case that one dolphin of the multipoint mooring system fails.

In Kato's experiment (Kato et al. 1996), the VLFS model is box-typed. It has a dimension of $L \times B \times D = 10 \text{ m} \times 2 \text{ m} \times 0.04 \text{ m}$ with the scale ratio of 1:50. The model is made of vinyl foam. The mooring system is composed of link devices and dolphins. The link devices operate with a fracture mechanism, which is able to disconnect when the compress load reaches a certain level. Springs are installed on the dolphins to simulate mooring stiffness. Universal joints are set at two ends of the link device, and they are able to rotate freely.

The model is fixed by seven dolphins. Four of them are set along the longitudinal side, while three others are located along the transverse side. Motions of VLFS are measured by two CCD cameras and LED (light emission diodes).

Accelerations at mooring point and forces on each dolphin are measured by accelerometers and force transducers, respectively.

Experimental Techniques of VLFS

The Law of Similarity

Ocean engineering model tests are commonly carried out in a basin including the following respects: At first, the characteristics of the prototype and the environment conditions must be simulated correctly. Then test data are acquired with scientific and effective measurement method. And the data acquired are carefully analyzed to achieve the conclusion needed.

Model tests use the physical model to obtain data needed for the design and construction of the ocean engineering structures. Therefore to obtain the correct information from the collected data, model test results must be transformed to corresponding values of the prototype. And this transformation must follow the law of similarity.

It is known that if all the parameters measured from one system (linear dimension, velocity, force, moment and time interval, etc.) could be achieved from another system by multiplying certain constant numbers, then the two systems may be regarded as similar (Liu et al. 1990). Mathematically, it can be expressed as:

$$\frac{L''}{L'} = C_L, \frac{V''}{V'} = C_V, \frac{T''}{T'} = C_T \dots$$

where, L, V, T – local or characteristic parameters relative to physical process;

Superscripts ' and '' indicate the parameters corresponding to the first and second system respectively;

C – constant similarity coefficients.

If the two systems are similar in physics, the law of similarity in kinematics and dynamics must be satisfied, i.e., the two systems are not only similar in geometry, but also in velocities, forces, and other physical constants in the problem. For vectors, such as velocity and force vectors, their directions at corresponding points must be consistent, in addition to their absolute values proportional to each other.

For hydroelasticity problems in ocean engineering, we know already the mathematical model to describe the interaction between structure and flow around it both for the model scale and full scale, therefore, we can obtain the similarity law from the formulation of the problem.

For simplicity and clarity, we use Timoshenko nonuniform beam or von Karman's isotropic thin plate as the structural model, and the motion equations of the freely floating beam or the plate can be taken as the dynamic boundary condition on the wetted body surface. If the two flow fields and structures for model and prototype are similar, the formulation of the problem posed above would be suitable for both of them and is complete.

For similar flow issues, we can use the relations given above to transform one system to another. The governing equation, kinematic boundary condition, seabed boundary conditions, and radiation conditions are self-similar, no required restriction is obtained. Thus, we need only focus our attention on the free surface condition and the motion equations of Timoshenko beam or von Karman plate.

Table 1 lists the characteristic variables between model and prototype usually used in ocean engineering experiment.

Design and Construction of VLFS Model

Before model tests, the scale ratio of model should be determined to obtain the test data needed. The scale factor is decided based on the balance among the wave-making condition of the basin

Experimental Techniques for VLFS, Table 1 Variables between model and prototype

Item	Symbol	Scaling ratio
Linear dimension	L_p/L_m	λ
Linear velocity	V_p/V_m	$\lambda^{1/2}$
Linear acceleration	a_p/a_m	1
Angle	φ_p/φ_m	1
Angle velocity	φ'_p/φ'_m	$\lambda^{-1/2}$
Period	T_p/T_m	$\lambda^{1/2}$
Area	A_p/A_m	λ^2
Volume	∇_p/∇_m	λ^3
Moment Inertia	I_p/I_m	$\gamma \lambda^5$
Force	F_p/F_m	$\gamma \lambda^3$

(the range of wave length L_w and wave height H), the required test condition of wave length L_w /ship length L_s , wave height H /ship length L_s , the possibility of reducing the structural rigidity of the model to the factor of $1/\lambda^5$, and the measurable strain range of the model in test wave conditions. Obviously, it is impossible to reduce the thickness of hull plate of the model exactly to the factor of $1/\lambda$, and to find the material with the Young's modulus of $E_m = E/\alpha$. Therefore, to simulate the global effect, the detailed layout and dimensions of the plates and stiffeners should be well designed to allow for the resultant flexural rigidity $E_m I_m$ and torsional rigidity $G_m L_{cm}$ satisfying the similitude conditions.

While transforming the test data from model scale into the full scale, the laws of similarity must be satisfied. To what extent the similarity conditions should be satisfied depends on the purpose of the test. To examine the loads and the structural responses of the structure in waves, no matter the interest is focused on the global reactions or local stresses, the geometry of global similarity of wetted surface, the hydrodynamic similarity of global motions, and the similarities of mass and stiffness distributions of the hull girder along the length, together with the radius of longitudinal gyration, must be satisfied (Wu et al. 2003).

In practice only part of the similitude conditions may be held, especially when an entire ship hull is to be modeled to the small size, due to the restrictions and limitations arising from the available materials and possible dimensions of the model.

During the wave tests, the gross weight of model should remain constant. So after model tests the model weight should be checked to ensure that the error between two measurements is less than 0.5%.

The gross weight of VLFS model consists of two parts: the VLFS model weight and the ballast weight. It should be noted that the model weight must be less than the gross weight. So during VLFS model construction, the model weight should be controlled carefully. After the model being constructed, the load conditions, the position of the center of gravity, longitudinal radii of gyration, and rolling periods can be adjusted at the

trimming table by adding or subtracting and/or shifting the weights so as to meet the specified requirements. For box-typed VLFS it can be regarded as an elastic body, and its longitudinal bending rigidity must be measured before storm tests and be transformed into full scale to simulate the prototype correctly.

After the model is adjusted, the weights should be numbered and fixed to ensure that the positions of the weights remain motionless during tests.

Main Facilities Needed in VLFS Model Tests

Main facilities needed in VLFS model tests include wave generator, wave absorbing beach, towing carriage, and noncontact optical systems for measuring motion, etc.

Wave Generator There are many types of wave generators all over the world. In VLFS tests in SJTU, a dual flap type hydraulic wave generator is adopted. The dual flap type hydraulic wave generator is made up of two flaps. One of the flaps is immersed in water and connected with the pedestal and swings around it. Another upper flap can swing around the fulcrum at the joint with the lower flap. The motions of two flaps are controlled by computers. Then complex waves of long crest can be simulated in water basin.

This wave generator is relatively advanced. But it is also complex and expensive. And it is also difficult for maintenance. In addition it must be water proof between the generator and the tank wall in order to avoid the water flowing behind the back of flaps.

Wave Absorbing Beach In order to absorb waves and avoid wave reflection, wave absorbing beach is set along the side opposite to the wave generator. There are many types of wave absorbing beaches in which the most common type is the parabola inclined plate. The gradient of inclined plane influences the wave absorbing performance directly. The wave absorbing beach with small gradient has better performance, but it will also cover more length of the basin. In addition the length of wave absorbing beach should not be too long. In order to obtain better performance, other types of wave absorbing beaches, such as dual

layers and multilayers are also adopted in some basins.

Moreover the wave absorbing beach should be easy to move, i.e., it would be not too large or heavy.

Noncontact Optical Systems for Measuring Motion Motions of VLFS model with six degree of freedom can be measured by the noncontact optical system. The system uses light emitting diodes and position sensitive detectors to measure the positions of several points of the model. Several LED are installed on the model and their motions are measured by noncontact optical system. Signals acquired are separated into data in 2-D multichannels, i.e., the projection location of LED (Yang et al. 1999).

This noncontact measuring system measures motions of VLFS model without forces acting on the model. Thus high precision can be obtained.

Examples of VLFS Model Tests

In this section, three model tests of VLFS are given. All these tests are carried out in the State Key Laboratory of Ocean Engineering, SJTU. The water basin is 50 m long, 30 m wide, and the main facilities include dual flap type hydraulic wave generator and large area false bottom. Water depth of the basin can be adjusted from 0 m to 5 m. The wave absorbing beach is located opposite to the wave generator and its performance is quite satisfactory.

Hydroelastic Model Test on Box-Typed VLFS (Chen et al. 2003; Chen 2003)

Design of the Test Model The VLFS model is of box-type, and its scale ratio is 1:100. The model is 10 m in length, 1 m in width, 0.05 m in depth, and

0.02 m in draft. Its bending rigidity is $EI = 5.79 \times 10^2 \text{ N} \cdot \text{m}^2$. According to the scale ratio, its prototype is 1000 m long, 100 m wide with a depth of 5 m. And the bending rigidity is $EI = 5.79 \times 10^{12} \text{ N} \cdot \text{m}^2$. The model consists of two layers. The upper layer is an aluminum plate with 4 mm in thickness, which simulates the rigidity needed and the lower layer is made of foam plastic with 4.6 cm in thickness supplying the required buoyancy. Outline of the model is showed in Fig. 1. Since its ratio of thickness to length is only 0.5%, so the influence of inhomogeneity due to different materials may be ignored. The model's exterior surface is covered with a waterproof layer, and its water permeability is about $1.4954 \times 10^{-5} \text{ kg}/(\text{m}^3\text{s})$.

Test Program The test mainly includes two parts: one part is the experiment of hydroelastic responses in regular waves and the other is the effect of water depth on hydroelastic behavior of VLFS. For the experiment in regular wave, water depth is 0.7 m, corresponding to the full-scale water depth of 70 m. Wave height is 2 cm, and the corresponding real wave height is 2 m and the wave period is 0.8, 1.13, 1.6, 1.96, 2.26, and 2.53 s, respectively, corresponding to the real wave period of 8, 11.3, 16, 19.6, 22.6, and 25.3 s. The ratio of wave length to the length of VLFS is, respectively, 0.1, 0.2, 0.4, 0.6, 0.8, and 1.0. Wave incidence angles are 180°, 165°, and 135°. The tests for the effect of water depth are carried out in regular waves. Wave direction is 180° only, and the ratio of wave length to VLFS length is limited to 0.4. Water depth is 0.2 m, 0.45 m, 1 m, and 2 m, respectively, corresponding to the wave depth of 20 m, 45 m, 100 m, and 200 m in full scale.

In this test VLFS model is moored as is shown in Fig. 2. The test setup is shown in Fig. 3.

Experimental Techniques for VLFS, Fig. 1 The VLFS model (unit: mm)

Experimental Techniques for VLFS, Fig. 2 Mooring of the VLFS Model

Experimental Techniques for VLFS, Fig. 3 The Setup of the Model Test

Altogether there are 21 displacement sensors placed on the model in longitudinal direction, 13 of them are placed in the mid-line of model. For the further research of transverse transformation, 5 others are placed along the transverse direction. And there are 4 sensors located at 4 corners of VLFS, respectively. The range of displacement sensor for measuring is about 0 ~ 10 cm and the nonlinearity is less than 0.2%. The six degree-of-freedom of VLFS model motions are measured by the noncontacted optical system. Wave height and period are acquired by the wave probe of resistance type. The effective duration of each wave test is 10 min at least in model scale corresponding to 100 min in full scale. All of the measurements are recorded in computer with a sampling rate of 20 per second. Part of the experiments results are shown in Fig. 4.

Model Test on Hydroelastic Responses of VLFS in Nonuniform Ocean Environment (Lu et al. 2004)

Design of Test Model The model used in this test is similar to the one described in the last

section. It also contains two layers with different materials. The upper one is a 2.5 mm aluminum layer, used to simulate the rigidity of the prototype, and the lower is a 27.5 mm foam plastic layer, supplying needed buoyancy. The VLFS model is 10 m long, 0.6 m wide, and 0.03 m in depth with a 0.01 m in draft. Its bending rigidity (EI) is $EI = 1.2573 \times 10^2 \text{ N} \cdot \text{m}^2$. While the full scale is 1000 m in length, 60 m in width with 3 m in depth and a 1 m in draft. Its bending rigidity is $EI = 1.2573 \times 10^{12} \text{ N} \cdot \text{m}^2$. In order to keep the weight of the model constant in storm tests, the surface is covered with waterproof layer, which has satisfactory performance of waterproof.

Some shoal models are set on the bottom of the basin to simulate the nonuniform ocean environment (see Photo 3 and Photo 4). Altogether there are three shoal models adopted in this experiment, which have different shapes and dimensions. Two of them are 2-D shoals with different dimensions, and the third is a 3-D shoal model. The 2-D shoal is a column with an elliptic section, while the 3-D one is a part of an ellipsoid.

Experimental Techniques for VLFS, Fig. 4 Distribution of maximum vertical displacements in different water depth (D -Draft, H -Water depth, T -Wave period, a -Wave amplitude, z -Vertical displacement)

Experimental Techniques for VLFS, Fig. 5 Arrangement of displacement sensors on VLFS model

Test Program VLFS is moored in the same way as shown in Fig. 2. There are 23 displacement sensors placed on the VLFS model. In the longitudinal direction, 13 displacement sensors are ranged in the mid-line of model, and there are 5 sensors located along the two sides. Motions and deformation are studied by measuring the

vertical displacement of every part of VLFS. The arrangement details are shown in Fig. 5.

Different wave incidence angles, water depths, and regular wave lengths are adopted in the experiment, and the relative position between shoals and VLFS model is also altered to study the influence of varied environmental conditions on the

hydroelasticity of VLFS. Wave height in model scale is 2 cm with the wave length in the range of 0.5 ~ 4.0 m, corresponding to the full scale 50 ~ 400 m respectively. The tests are run in waves with 180°, 150° and 120° headings. To study the effect of water depth on VLFS, water depth in experiment varies from 0.2 ~ 0.6 m corresponding to the real water depth of 20 ~ 60 m.

Multi-Module Test of Semi-Submersible VLFS (Yu et al. 2004)

Model Design A semi-submersible VLFS model is used in this test. The whole VLFS model is flexibly connected by three rigid modules (RMFC). This kind of connector system allows modules relative angular displacements in three directions, but their relative linear displacements are limited.

Each module is 2.75 m long, 1.25 m wide. Its depth is 0.575 m, and the draft is 0.288 m. The dimension in full scale is 275 m long, 125 m wide, and its depth and draft is 57.5 m and 28.8 m, respectively. The model is made of fiber glass reinforced plastics. Its load conditions, the position of center of gravity, longitudinal radii of gyration, and rolling periods are adjusted at the trimming table by adding and shifting the weights so as to meet the specified requirements. The setup of the model and connectors are shown in Figs. 1, 2, 3, 4, 5, and 6.

Test Program Semi-submersible VLFS in regular waves and irregular waves are tested. In regular wave tests the influence of wave period and direction on the motions and load of VLFS has been studied. And the irregular wave tests mainly focuses on the characteristics of multi-module VLFS in different wave directions and different connector rigidities.

In the test, noncontact optical system for measuring six degree of freedom motions is located on each module to measure their motions. Meanwhile, eight sets of 3-D force transducers are installed at the ends of four connectors to measure the connector loads. Its range for measurement is 0 ~ 50 kg and the accuracy is about 2.5% of the range. Wave heights and periods are measured with wave probe of resistance type. Its range is ± 30 cm and nonlinearity is less than 0.3%. Before the experiment, all these sensors are calibrated carefully.

Different water depth and wave heights are simulated according to the real operation environment and the theoretical calculation. And the water depth is 3 m corresponding to the full scale of 300 m.

Regular and irregular waves are adopted in the experiment. Regular wave height is less than 6 cm and the periods are 0.63 s, 0.70 s, 0.79 s, 0.90 s, 1.05 s, 1.26 s, 1.57 s, and 2.09 s. The wave height in full scale is not over 6 m

and the periods are 6.3 s, 7.0 s, 7.9 s, 9.0 s, 10.5 s, 12.6 s, 15.7 s, and 20.9 s correspondingly. The wave direction is also changed in the experiment to study the effect of wave incidence angle on the module motions and the connector loads. According to the test results of different wave height, RAO curves of VLFS motions and connector loads are obtained and compared.

Irregular waves are simulated according to the real environmental condition in operation and theoretical calculation. The Breschneider two-parameter spectrum is adopted as follows:

$$S_{\xi}(\omega) = \frac{1.25}{4} \left(\frac{2\pi}{T_p} \right)^4 \omega^{-5} H_s^2 e^{-1.25 \left(\frac{2\pi}{T_p \omega} \right)^4}$$

where T_p means spectrum peak period, H_s means the significant wave height.

In the experiment, the significant wave height of irregular waves is 1.88 cm and 3.25 cm, and the spectrum peak period is 0.88 s and 0.97 s, respectively. The significant wave height in full scale is 1.88 m and 3.25 m, respectively, and the peak period is 8.8 s and 9.7 s. Some photos are shown in Table 2.

Exploitation of Gas Hydrates

Gongkui Xiao

Department of Chemical Engineering, The University of Western Australia, Perth, WA, Australia

Definition

Gas hydrates are ice-like crystalline solids which consist of small molecules (typically gases) that are trapped inside “water cages” formed via hydrogen bonding (Sloan and Koh 2008).

Introduction

“Gas hydrates” is a common term for natural gas hydrates which are believed to be one of the most promising sources of fuel in the twenty-first century due to the enormous and untapped resources (Sloan and Koh 2008, Boswell and Collett 2011). A frequently quoted estimate of the global in-place natural gas resource volume contained in gas hydrates is about $2.1 \times 10^{16} \text{ m}^3$ (Milkov 2004), which is about twice the total proven worldwide resources of coal, oil, and natural gas. Natural gas hydrates have been found in both regions of permafrost and subsea sediments; however, the occurrence and amount of subsea gas hydrates (also known as marine gas hydrates) are much more than those in permafrost environment as shown by the US geological survey (Ruppel 2011). Gas hydrates can be found in different geologic environments, and their morphologies are different (Letcher 2013): They can be hydrate-filled networks of pores, massive hydrate lenses, grain-filling gas hydrate in marine sands, sea-floor mounds, grain-filling gas hydrate in marine clays, and grain-filling gas hydrate in onshore arctic sands/conglomerates. Marine gas hydrates can be found on continental slopes, land rocks (deep-water platforms), and basins in marginal waters of oceans, which have a water depth more than 350–600 m in the muddy seabed or in the loose sediment layer below the seabed. The

actual depth of hydrates occurrence depends on the temperature of water at these locations. Marine gas hydrates are not nice clear crystals but rather are muddy mixtures with sand, which is partly the reason that it is challenging to produce natural gas from them.

Structure and Thermodynamics of Hydrates

Natural gas hydrates are crystalline inclusion compounds, and they are nonstoichiometric. The methane molecules are caged by the hosting water molecules when the gas-water system is at high pressure and low temperature (Sloan and Koh 2008). The polyhedral cage-like hydrate lattices are formed via hydrogen bonding of water molecules and stabilized by the guest molecules. There are three common structure types (structures I, II, and H) for gas hydrates, which are largely determined by the type and size of guest molecules in the hydrate cages (Sloan and Koh 2008). For structure I, each unit cell is composed of 46 water molecules and 8 methane molecules. Other small gas molecules such as ethane and carbon dioxide can also form the type I structure. For structure II, each unit cell has 136 water molecules and 24 hydrocarbon molecules (Sloan 2011). The guest molecules in this structure can be propane and isobutane in addition to methane. For structure H, there is no consensus on the number of water molecules and gas molecules in each unit cell, and this type of structure could hold heavier hydrocarbons with more than five carbons in the molecules. Structures I and II are the most common gas hydrates in the oil and gas industry, while structure H is less common in either naturally occurring or artificial hydrates (Sloan et al. 2011).

Natural gas hydrates mostly exist in the form of structure I, as reported by Sloan et al. (2011), and they can be found at different combinations of temperature and pressure. Figure 1 shows the hydrate phase boundary curves of a pure water and methane system as well as a brine water (3.5 wt.% NaCl) and methane system, which was produced based on the predictions from

Exploitation of Gas Hydrates,

Fig. 1 Examples of structure I methane hydrate phase diagram for a pure water + methane system and a brine water (3.5 wt.% NaCl) + methane system

InfoChem's Multiflash 7.0 (KBC 2018). The "Hydrate Stable Region" is the temperature and pressure region wherein hydrates are in a thermodynamically stable state, while the "Hydrate-free Region" is the temperature and pressure region wherein gas and water coexist in different phases. The hydrate phase boundary is affected not only by the gas pressure and temperature, but also by the chemical composition of the water solution. The presence of salt decreases the required pressure for hydrate formation. It has to be cautioned that Fig. 1 is only an empirical phase equilibrium, and it should not be used directly for the prediction of hydrate dissociation because the hydrate formation process also involves kinetic effects (Lim et al. 2020). However, Fig. 1 could provide some guidance for the production of natural gas from methane hydrates, namely via either lowering the pressure of the gas in the hydrates system or increasing the temperature of the system to dissociate the hydrate to release the trapped gas. And for practical production planning, reliable gas and water solution compositions have to be obtained to decide proper exploitation routes.

Exploration and Production Trials

As they consist mostly of water (85 mol% water +15 mol% guest molecules), the physical appearance and density of gas hydrates are close to those

of ice (Koh et al. 2011). However, other physical properties, such as the shear coefficient, dielectric constant, and thermal conductivity, are lower than those of ice. In addition, the acoustic propagation velocity of natural gas hydrates is significantly higher than that of conventional gas sediments and saturated water sediments (Gabitto and Tsouris 2010; Wang et al. 2019). These differences are the theoretical basis for the exploration of natural gas hydrates by geophysical methods (Thakur and Rajput 2011). Geochemical methods could also be used for the identification of possible locations of hydrate formation (Yang and Sun 2011). Geochemical methods rely on the detection and analysis of the changes in the geochemistry of water bodies and sediments, which otherwise would be different from their normal properties if there were no hydrates because of the decomposition and crystallization of hydrates. Emerging marine technologies such as underwater imaging have also been applied for the location of hydrates deposits (Liu et al. 2020). Suitable methods should be selected for different environments and conditions, and sometimes a combination of methods should be considered to ensure the accuracy of exploration. The US geological survey shows that marine gas hydrates are most abundant in the Pacific marginal waters, followed by the Atlantic Ocean, on the edge of continental shelves (Ruppel 2011), which are favorable for gas hydrate formation because the sediments are

more developed and richer in organic matter and there are sufficient sources of methane-based hydrocarbon gases.

The production of methane from natural gas hydrates requires the release of methane from the hydrates formation in the seafloor before extracting the gas. Methods for dissociation of hydrates are largely based on the principles shown in Fig. 1, mainly including depressurization, thermal stimulation, and chemical stimulation (Moridis et al. 2009; Lee et al. 2011). The depressurization method is relatively simple to implement. It can be done by drilling a well for depressurization to favor the shift of the hydrate-gas phase equilibrium to the free gas side. However, the production rate of the depressurization method is slow because of the limited mass transfer and heat supply in the subsea environment. In addition, the depressurization method is not suitable for gas hydrate reservoirs where the reservoir temperature is near or below 0 °C, because the water may form ice at temperatures below 0 °C and the ice can retard the dissociation of hydrates and delay the transport of gas released from the hydrates (Yousif et al. 1991; Li and Han 2019). Thermal stimulation is another method to help release gas from the hydrate formation. This method requires the supply of heat to decompose the hydrates; therefore, it is also called thermal excitation method or thermal decomposition method. The heating methods mainly include the injection of steam, hot water, and hot brine as well as electromagnetic heating. This method can release gas faster than the depressurization method, but the limitation is the high heat loss and low thermal efficiency (Lee and Holder 2001; Uchida et al. 2004). Chemical stimulation method involves the injection of chemicals that will break the molecular cage formed by the water molecules, and they are essentially the same as those used for flow assurance purposes (Koh et al. 2002). However, extra care must be taken to ensure the injection of chemicals would not contaminate the subsea ecosystem. In recent years, an additional approach of releasing CH₄ from natural gas hydrates is proposed, and it is commonly referred to as carbon dioxide hydrate replacement for methane hydrate (Zhao et al. 2012; Komatsu et al. 2013). This method recovers CH₄ through the

dissociation of methane hydrates caused by the heat released from the formation of carbon dioxide hydrates, which is because carbon dioxide preferentially (compared to methane) forms hydrate since the temperature and pressure conditions required for CO₂ to form hydrate are much lower than those for methane. This method is being actively investigated at the laboratory-scale because of its potential of sequestering CO₂ and producing CH₄ at the same time.

To date, well-known trial productions from natural gas hydrates have only been carried out in two permafrost areas and two marine areas. Chronologically, the first production trials were from permafrost gas hydrates in the Mackenzie Delta region in Canada, which were carried out three times in 2002, 2007, and 2008; the second was the 2012 permafrost trial in the Alaska North Slope region in the United States; trial productions from marine natural gas hydrates were carried out in the Nankai Trough in Japan in 2013 and 2017; then more trials from marine hydrates were tested by China in the Shenhu area in the South China Sea in 2017 and between October 2019 and April 2020.

Both thermal stimulation and depressurization methods were used in the Mackenzie Delta trials (Dallimore et al. 2012). In 2002, the thermal stimulation method was used and 463 m³ gas (at standard conditions) was produced in 5 days. In the 2007 and 2008 trials, the depressurization method was used. In 2007, 830 m³ gas was produced in 12.5 h; and in 2008, 13,000 m³ gas was produced in 6 days. The trials were eventually aborted due to the blockage of the pipeline by the coproduced sand. The Alaska North Slope trial used the CO₂ and methane hydrate replacement method, which was the first notable field trial (Boswell et al. 2017). A mixture of CO₂ and nitrogen was injected into a reservoir, and CH₄ was produced along with water and sand. Some exchange of CO₂ with CH₄ in the hydrate phase had occurred; however, the low exchange rate of CO₂ and CH₄ has limited the overall CH₄ production rate and recovery. Therefore, depressurization was later used as an auxiliary method and the trial produced 24,000 m³ gas in a month. The 2013 Nankai Trough trial extracted 120,000 m³

gas in 6 days using the depressurization method, and the trial was forced to stop due to the sand production problem. Another two trials in the same area were carried out in 2017. In May, 35,000 m³ gas was produced in 12 days, and the operation was shut down due to the same sand production problem. In June, 200,000 m³ gas was produced in 24 days. Although there was no sand problem, the production rate of methane was low (Oyama and Masutani 2017). In May 2017, China conducted its first test of gas production from marine gas hydrates using the depressurization method in the Shenhu area in the South China Sea. In 60 days of continuous gas production, 309,000 m³ gas was produced, which includes both methane from the decomposition of natural gas hydrates and the free moving gas below the hydrate layer. China conducted a second test in the same area between October 2019 and April 2020, and 86.14×10^4 m³ gas was produced in a 30-day continuous operation (Li et al. 2018; Ye et al. 2020).

Technical and Environmental Challenges

The highest daily average rate of all the production trials is 28,700 m³/day, achieved in the second test in the Shenhu area. However, this production rate is still far less than the commercially viable rate, which needs to be more than 100,000 m³ gas per day for a single gas well. The low gas production rate from gas hydrates mainly arises from the slow decomposition of the hydrates and the coproduction of sand and the blockage of gas and water pipelines (Letcher 2013). Therefore, it is critical to understand the geological parameters of hydrate reservoir in addition to the thermodynamics of hydrates so that appropriate production technologies could be selected (Moridis et al. 2011; Lau et al. 2018). Meanwhile, the gas extraction technology and process also need to be improved to increase production efficiency, especially the way of preventing or reducing the intrusion of sand into the production line. Although potentially improved methods could be tested in laboratory, they must be validated in real production trials, which is a

potentially major obstacle for deploying because these field tests may require significant resources and collaboration. Another technical challenge to produce gas from marine hydrates is the unconsolidated nature of the hydrate reservoirs because of the dissociation of gas from hydrates, which may cause the reservoir to lose its mechanical strength such that the production well may collapse and cause the loss of production equipment. To understand and overcome these challenges, both experimental and numerical simulations of the hydrate reservoir conditions need to be performed. It was reported that experimental and numerical simulations have showed that new technologies such as horizontal wells and multi-branch wells (Maricic et al. 2008; Reagan et al. 2008), which have been widely used for coalbed methane extraction, can increase the production capacity by five to six times. However, as most subsea hydrates are shallow and soft sediments, further geological data are required to support the construct of such wells in practical operations.

The environmental impact of producing methane from natural gas hydrates has attracted the attention from governments and scientists, with concerns such as sudden release of large amount of methane from the seafloor, damage to the marine ecosystem, impact on the global warming, and subsea geological disaster (Li and Han 2019). It is possible that a large amount of gas is suddenly released from the subsea hydrates when the stability of the hydrate area is disrupted by the exploitation of gas. Such a gas release will cause the seawater to fluctuate drastically, producing an effect like an earthquake in the seafloor. To avoid this, proper real-time monitoring of the production site and the adjacent area is essential. However, it must be noted that there is no evidence that gas hydrate production could lead to uncontrolled hydrate dissociation and gas release to the sea water (Ruppel and Kessler 2017).

The marine ecological environment may also be adversely affected by the leaked methane into the water body (Yamamoto et al. 2014). Most of the methane that enters the seawater will react with oxygen to produce carbon dioxide when there is sufficient oxygen in the water body. The consumption of oxygen in the seawater will result

in the depletion of oxygen, which is a direct cause of the extinction of certain marine life. Therefore, there is a concern that the exploitation of natural gas hydrates may affect the ecological balance of the ocean and lead to the extinction of some marine organisms.

Another concern about the potential environmental impact of developing natural gas hydrates is the impact on climate. Although methane consists a small percentage of the atmosphere, it has a much greater greenhouse effect than carbon dioxide; it is 28–36 times greater than that of carbon dioxide over a 100-year period (Balcombe et al. 2018). The extraction of natural gas hydrates will inevitably result in the release of methane into the atmosphere, just as much as the conventional gas industry if not more. The warming effect of methane decreases with time due to chemical reactions in the atmosphere (Holmes 2018); however, proper measures should be taken to reduce the emissions since any more methane in the atmosphere is going to have an impact on the oceans and could lead to a global warming trend exacerbated by the dispersion of gas hydrates.

Natural gas hydrates affect the physical properties of the sediment (Gabbito and Tsouris 2010); thus, hydrates will have an impact on the stability of the seafloor. The hydrates are stable under certain pressure and temperature conditions, but their dissociation for gas production may cause geological disaster (Maslin et al. 2010). Gas hydrates are also related to the safety of offshore oil and gas facilities. A small change in pressure or temperature caused by oil and gas production can cause fracture of the gas hydrate layer, resulting in well blowouts, subsea collapse, and coastal landslides, which are not rare scenarios in the gas production history. Therefore, geological monitoring of the natural gas hydrate production site is important to avoid potential problems (Sun et al. 2020).

Concluding Remarks

Natural gas hydrate is a crystalline substance formed between various hydrocarbon and non-hydrocarbon substances and water molecules

under low temperature and high-pressure conditions. Methane is the most common and the most abundant gas in natural gas hydrates, which could be an alternative energy source in the twenty-first century, and their successful development may provide energy security to countries with large hydrate resources. Marine gas hydrates are overwhelmingly dominant, and they are found in water depth below 350–600 m in the muddy seabed or in the loose sediment layer below the seabed. As the hydrates are commonly mixed with muddy sand, it is challenging to efficiently produce natural gas from them. Most natural gas hydrates have type I structure, which has relatively well-understood phase equilibrium properties that can be used as a guide to produce gas. Natural gas hydrates have been found in many locations around the world, but there is no commercial production operation yet although several trial productions have been carried out. A few technical and environmental challenges need to be tackled before commercial production of methane from hydrates. As a new energy source with great potential, natural gas hydrates undoubtedly have a very broad development prospect. If the production and environmental challenges are solved, natural gas hydrates will become a new treasure in the energy field in the future.

Explosive dismantling

Definition

To remove a fixed platform, the installation steps are essentially reversed. Topside equipment such as living quarters, generators, and processing equipment is taken off by crane and returned to shore for scrap or to be reused. The deck sections are then lifted from the platform and placed on cargo barges for transportation to their disposal site. Conductors, flare piles, well conductors, submerged wells, and caissons are structures subject to explosive removal (MMS 2004).

Scientific Fundamentals

The History of Explosive Removal

Nowadays, a large number of offshore structures are in operation to exploit oil and gas all over the

world. However, the operator may make a decision to terminate and remove the offshore productions from a producing field if they are not uneconomic any longer. Therefore, most of the platforms carried out to be removed are located in shallow water depths (less than 200 meters). Considering the movement of offshore production platforms and recent interests in deepwater development are increasing, it led to a thinking about how to remove the platform in deeper OCS (Outer Continental Shelf) waters (e.g., over the continental slope) (MMS 2004).

Explosive removal is considered as a conditional and common method to remove the useless offshore structures (shown in Fig. 1). The removal of the offshore structure (platform or ship) usually requires explosives to remove structural components in a few feet below the bottom of the sea, such as wellhead, pile, etc. In addition, considering the presence of endangered species or threatened species which are listed or proposed to be included in the America's Endangered Species Act in protected species in the ocean as well as the requirements of reducing or eliminating the influence on these species, the environmental impacts associated with explosive platform removal needs to be fully understood and attached important to.

Procedure in removing a fixed platform is basically reversed compared to the installation steps. Topside equipment such as living quarters, generators, and processing equipment is removed with a crane and back to the shore for scrap or reused. Then the deck sections are lifted from the platform and placed on cargo sailing to the disposal site in the transportation. Conductors, flare piles, submerged wells, and caissons are also structures to be removed with the use of explosives. The regulations of Minerals Management Service (MMS) in the USA make a requirement that piles and well conductors shall be severed at least 5 m below the mud line (MMS 2004). The piles and conductors are lifted and board on a cargo barge for the use of ultimate disposal once they are separated from the seabed.

The current researches focus on collecting and synthesizing existing information for explosive removal of offshore structures in aquatic

Explosive Removal,

Fig. 1 Explosive removal of offshore structure (MMS 2004)

environments. A more detailed illustration of explosive removal will spread, including the techniques, characteristics of underwater explosive removal, and impacts on the environment in this paper.

Explosive Removal Techniques

Placing an explosive charge inside the offshore structure at the desired depth and severing the explosively is the safest and easiest way of cutting procedure (MMS 2004).

Severing of piles and conductors in the underwater environment is a slow and dangerous process for the reason that it requires mass of diving time and divers will bear enormous risks. The explosive removal technique is the key point of the development of explosive removal. At present, it can be summarized into bulk explosive, configured bulk explosive, and cutting charges.

Bulk Explosive

Bulk explosives such as C-4 or Comp B (Fig. 2) are the most common techniques for explosive cutting of piles and conductors. These explosives are plastic and fabricable which have a high velocity on detonation and a high shattering power. Compared to other types of high explosives, they are less dangerous to handle. In addition, bulk explosives can be molded in the field and made into specific sizes and shapes. Compared with

Explosive Removal, Fig. 2 Bulk explosive (DEMEX 2002)

conventional cutting techniques, the important advantage of explosive technology is plasticity. During the construction of the platform, piles are welded together with a steel guide (called “stabbing guides”) on the inner bottom of each pile to facilitate the matching of the next part. In this way, the inside diameter of the pile is reduced inside

and outside the weld. The reduction in inner diameter of the pile is of great importance when conventional cutting techniques are used where the equipment shall be lowered along the pile and retrieved after cutting is finished. Variations in pile diameter are relatively inconvenient when bulk explosives are used. Bulk charges can be resized to sever a pile on the scene and do not have to be retrieved. Bulk charges can also be reshaped on the scene when the difference between the “planned” and the “as built” diameters of piles or well strings is encountered. The operation proceeds with relatively little delay owing to the flexibility; thus the flexibility is very important. Another advantage of bulk explosive is its high success rate, which is about 95% if sized properly. Furthermore, the increase in water depth has no adverse impact on the success rate of bulk explosive cuttings.

Configured Bulk Explosive

Configured bulk explosive includes “ring explosive” and “focusing explosive.” It is designed to collide the detonation front in order to concentrate more energy along the fracture line; the size of the charge carried to sever a piling is reduced consequently. The charges of these types proved to be effective in reducing belling or bulging out of the severed piling.

Ring Explosive The materials of ring explosive (shown in Fig. 3) are the same with that used in bulk explosive (shown in Fig. 3), which are mainly C-4 or Comp B and lowered into the piling. These rings concentrate the explosive closer to the inside of the piling’s walls, making the explosion process more effective. The total weight of charges required to sever a specific piling can be reduced by 10–15% approximately with ring charges (NRC 1996).

Focusing Explosive Focusing charges (shown in Fig. 4) are the sandwiched structures consisting of explosives between two tamping plates, one above and the other below. The use of smaller charges is accepted because these tamping plates have the function of delivering more power of explosive to the piling walls horizontally.

Explosive Removal, Fig. 3 Ring explosive (DEMEX 2002)

Explosive Removal, Fig. 4 Focusing explosive (DEMEX 2002)

Reductions in explosive weight with focusing plates are comparable to reductions in weights associated with ring charges. The weakness with both ring and focusing charge arrangements is that they must be prefabricated and sized to fit each application. Generally, each configuration varied in size which will allow for minor variations of inside pile diameters or obstructions. The

drawback with both ring and focusing charge arrangements is that the charges must be pre-fabricated. It is difficult to employ the configured charges to cut off wells due to the small diameter of the inner casing (NRC 1996).

Cutting Charges

Cutting charges include linear-shaped charges and cutting tape, each of which will be discussed with more details below. Compared to explosive cutting, mechanical cutting is less reliable, and the risk of failure is much higher (Kaiser et al. 2002). In addition, potential future explosive cutting techniques cover contact plaster, shock wave focusing, and radial hollow.

Linear-Shaped Charges Linear charges use high-speed explosives as energy to accelerate the v-shaped strip of cutting materials, through the pile-driving steel with high-speed jet flows. The linear-shaped charges can be used in a specially manufactured container which is assembled around the outside of the piling to sever the pile from the outside (shown in Fig. 5a). With the help of a positioning tool, linear-shaped charges can also be placed inside platform legs (Fig. 5b).

The performance of linear-shaped charges is relevant to the presence of an air space between the charge and the target. This standoff distance required is a function of the thickness of the material to be severed. When the standoff distance between charge and target is accurately positioned

and precisely calculated, the linear shape of the charge produces a very smooth cut (NRC 1996).

Lead time of linear-shaped charges is quite long, and accurate engineering data of piling or caisson to be cut is needed. If the thickness of a pile section is unknown or the pile is not round, the cut produced by a linearly shaped charge will not be clean. If linear-shaped charges are placed outside a piling, the explosive power provided by soil will not attenuate. Linear-shaped charges must be hinged to pass through the stabbing guides to be used inside a piling. A clean cut cannot be obtained if a stabbing guide is located at the height of the proposed cut. Furthermore, it will lead to a great performance degradation of charging if water or soil permeates the air space at a distance.

Cutting Tape Explosive cut tape is a flexible form of linear charge (Fig. 6). The explosive and the liner are squeezed into a shape charge that is fixed in a flexible conductor, allowing the tape to form a profile with the pile, thus keeping a proper distance around the entire pile.

There are two disadvantages of cutting tape (MMS 2004):

1. The diver is required to place the tape around the target pile.
2. As the charge and the liner are located on the surface of the conductor and the depth is greater than 91 m, the environmental pressure may cause the conductor to deform, thus

Explosive Removal,

Fig. 5 (a) External linear-shaped charge (DEMEX 2002) (b) Internal linear-shaped charge (DEMEX 2002)

Explosive Removal, Fig. 6 Flexible linear-shaped charge (DEMEX 2002)

changing the spacing and reducing the charge cutting efficiency.

At this point in time, cutting tape is less efficient than linear charge removal platforms, especially in the sea areas where the depths are more than 91 meters (NRC 1996).

Key Applications

Explosive Process

Most explosives used in underwater explosions contain oxygen and have relatively unstable chemical bonds (MMS 2004). When the explosion began, oxygen was easily released and recombined with other atoms to form more stable molecules. The explosive reaction is the breaking down of the original molecules into derivatives, which is accompanied by the release of large amounts of heat.

Physical impact caused by detonating explosives, which trigger the release of chemical energy, so as to realize self-sustaining wave, is known as the detonation wave. It is different from the shock wave propagating by non-reacting media, in which conditions the chemical transformation of energy release affect the shock front. The wave is not driven by the motion of the

boundary surface behind the shock wave, but the internal conditions of the matter behind it. At a relatively close distance from the explosion, the charge diameter of the explosive is generally considered to be three to ten times, and the direct explosion effect generated by the explosion can be neglected. The main source of shock around this distance is the gas reaction product of shock wave and expansion.

Shock Wave and Propagation

Pressure Waveform

The main shock pulses have rapid rising time and exponential decay, which are followed by a series of bubble pulses (MMS 2004). This high-pressure pulse is formed by the rapid conversion of solid explosives into gas form. The negative phase pressure after the impulse is due to overshoot. When the bubble reaches its maximum volume with the minimum of the negative phase, it begins to collapse. When the bubble reaches the minimum volume with the second peak in the pressure waveform, it would be called the first bubble pulse. This oscillating behavior continues, although the amplitude pulse decreases as the energy dissipates.

Sea Surface Reflections

The sound wave energy of sea surface reflection coefficient is close to negative 1 atmosphere, which indicates that the reflection phase is reversed 180° and the incident pressure pulse is reflected in reverse polarity. Surface roughness causes reflected scattering. In addition, bubbles near the surface can absorb sound waves or scatter reflected energy as a result of the wave's rupture. Therefore, for high-frequency sound, roughness is usually more important than low-frequency sound (MMS 2004).

Sea Bottom Reflection

For the seafloor, the impedance contrast between surface and seabed material is smaller than that between surface and air. As a result, a large number of acoustic energy events occurring on the seafloor will be transmitted to the seafloor, where it may be reflected back from beneath the

seafloor. A good summary can be found in Brekhovskikh (1980). From the research of Brekhovskikh, the bottom reflection coefficient under steep angle is true and positive, while the bottom reflection coefficient under shallow angle is much more complex.

Impacts to the Marine Environment

The environment problem is serious and non-negligible to the global world, while the impacts to the marine environment may be the biggest disadvantage of explosive removal, which have been paid close attention by people from all walks of life. Explosive removal of ocean structures affects marine life, including fish, turtles, and marine mammals. A large number of studies have been conducted to study the effects of explosive removal on the marine environment. Dzwilewski and Fenton (2003) proposed a method that can accurately simulate the shock wave effect of explosive under the mud line of piles, legs, pipes, or other structural units. A method for calculating explosive effect by using the function of pile diameter, wall thickness, and weight of explosive is presented.

Impacts to the Fishes

Young (1991) conducted experiments to apply impact pressure to different types of fish in order to establish a damage prediction model. These studies show that the cube root scale is effective for the near distance of electric charge, but the effect of sea surface sparse waves and seafloor reflection may play a greater role in the larger distance, which should be considered in the long-distance prediction.

Impacts to the Sea Turtles

The researchers predicted that the eardrums of turtles are sensitive and that small turtles are more vulnerable to shock waves than large turtles. The dominant sea turtle in the USA observed during the removal of the explosive structure is the loggerhead, which is listed as an endangered species. On account of sea turtles' characteristic of behaviors, it is difficult to observe and estimate the impact of explosive removal on sea turtles. Sea turtles in temperate regions generally spend less than 10% of their time on the surface of the water

(Byles 1989; Kemmerer et al. 1983; Nelson et al. 1987; Renaud and Carpenter 1994). The injured turtles, who were able to swim, returned to the sea, and the dying ones sank to the bottom. In addition, explosives can detonate within days, weeks, or even months as the platform is dismantled, and bodies can be carried away by water or predators from the area. Without a thorough investigation of the seabed after each explosion, only a conditional assessment of the impact can be made (Gregg et al. 1997).

Edward (1988) counted and analyzed the impact of offshore oil platform explosion on sea turtles and dolphins, during the period of high and low sea level explosion from March to April 1985 to March 1988. The results showed that there was a positive correlation between the frequency of stranding and explosion of sea turtles. Dates and locations for the use of underwater explosives in offshore oil and gas structures are available throughout industry documents. No government agency or agency has a complete database for explosions in offshore waters and coastal areas, and even if autopsies are carried out, the cause of death cannot be determined.

Impacts on Sea Mammals

O'Keeffe and Young (1982) hypothesized that shock waves damage the lungs and other organs for the sea mammals. Research at Lovelace Institute for biomedical and environmental research on the effects of underwater explosions on dogs, sheep, and monkeys has shown that as a function of sample size, species respond similarly to shock waves. Two types of damage caused by underwater explosions are hemorrhage in the lungs and around the lungs and stimulation of radial vibrations in small bubbles that normally exist in the intestines (Yelverton et al. 1973, 1975).

External Turret

Shuqing Wang and Xiancang Song
College of Engineering, Ocean University of China, Qingdao, China

Definition

The *external turret* is a system where the “CALM buoy” is fixed to a cantilever yoke at the bow or often on an increased height above the bow (gooseneck structure) of the moored tanker. It is widely used to maintain the floating production, storage, and offloading (FPSO) on station especially in shallow water.

Scientific Fundamentals

Introduction

FPSO, which is first applied in 1977, is generally used to separate and process the oil and gas from the extracted oil, storage, and transport of crude oil products (Liu and He 2006). In order to maintain the operational capability, the turret mooring system is often adopted for FPSO station keeping. Depending on the type of vessel and its operations location, the turret system can be divided into internal and external turret. It includes a turret system that is located at the extreme end of an outrigger structure attached to the bow of the

External Turret,

Fig. 1 External turret mooring system (www.sofec.com)

vessel, as illustrated in Fig. 1 (Bluewater 2009; Wichers 2013).

An advantage of the external turret system over other options for floating installations such as spread mooring is that it allows the vessel to rotate and adopt the optimum orientation in response to weather and current conditions. This rotation of the vessel about the turret is known as weathervaning. It is less expensive than internal turret designs and can be delivered in a shorter period of time, making it an excellent choice for many applications (Shimamura et al. 2006).

Components and Function of the External Turret System

Main Components

As shown in Fig. 2, the external turret system usually includes following four parts (Wall et al. 2002)

- **Turret (T):** This provides the single-point mooring and allows weathervaning of the vessel. It includes the turret shaft, turret casing, main and lower bearings, and the mooring spider.
- **Fluid transfer system (FTS):** This is typically a multiple swivel assembly. It transfers the process fluids and other signals from the turret to the process plant on the vessel. It is positioned above the turret and linked via the turret transfer system.

- **Turret transfer system (TTS):** This refers to the intermediate manifolding linking the turret and the FTS. It is often positioned on a turntable on top of the turret. It rotates with the turret. It is otherwise referred to as the turntable or turntable manifolding.
- **Interfacing systems (IS):** This includes swivel access structure, mooring lines and flexibles below the turret, and other ancillary equipment.

Function

The external turret system performs four main functions in a typical FPSO:

- Maintaining the vessel on station through single mooring
- Allowing weathervaning or rotation of the vessel to adjust to climate conditions
- Fluid transfer from the risers to the process plant
- Providing transfer of electrical, hydraulic, and other control signals

External Cantilevered Turret

It is possible to classify three main types of external FPSO or FSU turret, including external cantilevered turret (ECT), external disconnectable turret (EDT), and external wishbone (EW). Of the three main types of external turret designs, only the first two are currently widely used (Wall et al. 2002).

External Turret,**Fig. 2** Main components of external turret system (Wall et al. 2002)

The external turret is cantilevered from the bow of the vessel in a similar manner to a conventional external turret as shown in Fig. 3. The system will usually use a single or multipath swivel as a fluid transfer and have a simple turret bearing system.

Device Components

The ECT turret might typically comprise the following devices:

- Cantilever support
- Conventional multipath swivel
- Turntable and manifolding
- Bearing support and turret bearing
- Risers
- Chain table
- Winch for connection
- Mooring chains

The swivel is assembly mounted on a cantilevered support structure attached to the bow of the vessel. Mooring connections to

the turret provide single-point mooring to the seabed and allow the vessel to rotate freely around the turret adjusting to climatic conditions. The risers from the well are connected to the swivel. FPSO vessels of this type with conventional or multipath swivels can take oil production from several wells.

Design Principle

The turret design is generally smaller and handles fewer flow paths than internal turret. The main difference is that the turret is located at the end of a cantilevered support structure and not in a cavity in the vessel itself.

Pipework and turret are exposed, so corrosion of manifold pipework and inaccessible pipework in the cantilever area is of specific concern. Bearings will usually be of a roller design.

The principal features include:

- External cantilevered turret elevated above water level at the bow of the vessel
- Multipath swivel for FTS

External Turret,

Fig. 3 FPSO with external cantilevered turret (ECT) (www.sofec.com)

- Conventional turret bearing and support
- Multiple wells
- Articulation via universal joint to accommodate riser movement
- Mooring by conventional anchor chain and wire catenary mooring
- Isolation valves on each riser

Safety Concerns and Maintenance

The process plant and accommodation on the vessel is downwind of the turret and is a safety consideration. Consequences of hydrocarbon leakage could escalate if not controlled and appropriate evacuation procedures put in place. The turret is exposed at the bow of the vessel and susceptible to green water or wave damage and corrosion from seawater.

Typical maintenance for an external cantilevered turret may comprise:

- External visual examination of the turret for corrosion damage
- Functionality check on turret bearing and including torque checks
- Grease monitoring of turret bearings
- Examination of the swivel and dynamic seal performance
- Replacement of static seals
- Examination of flexible risers as recommended by the manufacturer particularly connections
- Leak monitoring of the riser connections, the interfaces, the manifolding, and the swivel
- Diver examination, or recovery and examination, of the mooring chains and connections
- Visual inspection of pipework in cantilever structure for corrosion damage

Disconnectable External Turret

Figure 4 is an external disconnectable turret. This is similar to the external cantilevered turret but has a tensioned riser connector that enables the riser and moorings to be quickly disconnected and allows the vessel to sail away from the station (Shimamura et al. 2006).

Device Components

The components are the same as for the external cantilevered turret (ECT) with the following additions:

- Connection/disconnection interface
- Tensioner
- Locking mechanism
- Universal joint to control riser orientation
- Riser column
- Winch for reconnection

This disconnection interface between the riser column and FPSO is a structural connector usually based on a hydraulic collet-type connector

External Turret, Fig. 4 FPSO with external disconnectable turret (ETD) inset (Wall et al. 2002)

typically 50–60 in. in diameter. The articulations of the riser column are accommodated by a universal joint mounted on the rigid arm turntable structure at the bow of the FPSO. The mooring loads are transmitted from the structural connector to the main bearing via the universal joint to the bearing support structure.

The universal joint is adopted to control the orientation of the risers relative to the turret. It is an important load bearing component, and any damage would affect the weathervaning of the FPSO.

The riser column supports the chain table, and the anchor legs once disconnected form the FPSO flexible, or conventional risers may be used.

The typical configuration of the external turret is that a gear ring located on the rigid arm turntable controls the orientation of the main connector and the fluid transfer connectors. Risers between the seabed PLEMs and the riser RTM are flexible hoses in a steep wave configuration. Risers are routed through J-tubes or to hard-pipe connections at two levels on the riser column. The disconnection interface is at the top of the riser column at the main structural connector level. All flow lines are routed through flow line

connectors with integral isolation ball valves through jumper hoses around the universal joint.

The riser column is reconnected by means of a linear winch. The reconnection wire rope is winched through the connector, universal joint, and swivel stack over the top pulley mount onto the support structure above the rigid arm. Once the connector flanges are face-to-face, the turntable structure is rotated to align the flow line connectors, and the structural connector is locked. Each flow line connector can then be connected individually.

Design Principle

The principle of operation is the same as for the external cantilevered turret (ECT) with the additional feature that the turret system can be disconnected from the FPSO in severe storms/cyclones, or for scheduled dry dockings. This allows the vessel to sail away under its own power. Disconnection of the turret system can be carried out from the FPSO bridge or locally at the bow. Reconnection is performed without the need for external assistance.

Such a turret design may be used on a site subject to seasonal cyclones. While connected the turret may be able to endure a sea state equal to a 10-year non-cyclonic storm (e.g., significant

wave height 4.5 m, current 1 m/sec). While disconnected, the mooring buoy is able to withstand a 100-year cyclonic condition with one damaged chain (i.e., significant wave height 10 m, current 2.5 m/sec).

Safety Concerns and Maintenance

The operational and safety concerns are the same as for the external cantilevered turret (ECT) with additional issues associated with connection and disconnection. The ability to connect and disconnect is a key part of safety cases. There is the potential for hydrocarbon release during connection and disconnection. The production and the swivel would be shut down and isolated before disconnection. Disconnection is a safety measure in the event of hydrocarbon leakage in the turret or manifolding systems.

Maintenance and inspection practices are the same as for the external cantilevered turret (ECT) with the following additions associated with the disconnection interface and universal joint:

- Check functionality of connection/disconnection interface
- Check functionality of turret bearing and universal joint including torque checks
- Check integrity of all riser connections and interfaces
- Diver examination or recovery and examination of mooring chains and connections
- Check function and maintain winch for connection/disconnection

Conclusions

The external turret is a vital component of the single-point mooring systems for the ship-based floating production systems in moderate to harsh environments, and it allows the floating systems to weathervane and align itself in the direction of minimum loadings. Furthermore, the external turret can be designed to be disconnectable so that the floating system could be moved to a protective environment in the event of a hurricane or typhoon. Due to the complexity of the external turret, further research on structural optimum

design and safety assessment and management is still significant to ensure the safe, reliable, and high efficiency operation of the ship-based floating system.

External Turret Single Point Mooring System

Yougang Tang
Tianjin University, Tianjin, China

Synonyms

[Mooring system](#); [Positioning system](#); [Single point mooring system](#)

Definition

The device is a type of single point mooring system and belongs to the turret type single point mooring device. This type of single point mooring is moored to the seabed by a turret outside the bow (tail) through a uniform or grouped anchor chain. The FPSO hull rotates 360° around the external turret under wind, wave, and flow environmental loads, with a weather mark effect, which allows the hull to adjust to the direction of the least force. Because the single point mooring buoy and turret are installed outside the hull, it is called the external turret single point mooring system. The external turret single point mooring system is divided into a riser type and a cantilever type based on the structure type. The crude oil enters the oil storage tank through the submarine pipeline into the rotary sealing joint in the external turret.

Development History

In the early 1980s, SBM first proposed the concept of a turret based on the principle of “wind-mark effect.” In 1985, an external turret was installed in the stern of a 140,000-ton floating storage tanker, applying this concept to reality (Yifeng 2012; Liu and He 2006).

The turret mooring works in the same way as other single point mooring methods. It also fixes the tanker to the mooring point at sea through a certain connection, so that it can rotate freely in all

directions with the action of wind, waves, and water current. The weather mark effect is formed to avoid the destructive force caused by wind and waves, thereby reducing the environmental load and motion response of the system under the external disturbance force of wind and waves. The turret mooring system is mainly composed of four parts: turret, liquid transmission system, turret rotation system or rotary table, and interface connection system. The turret is not only the mooring point of the tanker but also the passageway of the riser and other umbilical system to the hull deck through the seabed. The relatively fixed characteristics of the pontoon and the deck facilities ensure that the oil tankers can also achieve continuous oil and gas transport between the seabed wellhead under complicated sea conditions, which is the core of turret mooring technology. Compared with many other mooring methods, the turret mooring system has the following advantages: (1) simple structure; (2) less influenced by waves, suitable for severe sea conditions; (3) applicable to various water depths; and (4) it has a quick release and reconnect function for easy maintenance (Liu and He 2006; Liu 2012).

The traditional external turret mooring system is the external disconnectable riser turret mooring system. As shown in Fig. 1, it first appeared in 1986, mainly composed of overhanging turret, articulated head connector, cylindrical mooring riser, mooring chain, universal joint, rotary joint, and mechanical connecting device. It was applied to the development of the H59IJ3 oil

External Turret Single Point Mooring System, Fig. 1 Riser-type detachable external tower mooring system

field in the hurricane area of the northwest coast of Australia, thus opening the door to the development and utilization of turret mooring technology.

The advantages of the retractable riser-type external turret mooring system are less investment, easy to manufacture and demolition, release and return function, and mitigation of mooring characteristic of the mooring characteristics. The shortcoming is that after the system is released, because the riser displacement is much larger than the weight of a single point, there is a large residual buoyancy. The existence of the residual buoyancy makes the movement of the riser under the action of waves difficult to control, which is not conducive to the return installation of the riser type external turret mooring system.

After several decades of development, the external tower mooring system has been greatly improved. The external turret currently used is mostly an external cantilevered turret (ECT), as shown in Fig. 2, which is a permanent mooring system. The main feature is that the bow or stern is fitted with a large outrigger structure that can

accommodate the rotating bearing and the external turret. This supporting structure makes the turret out of the water (Lian-zheng et al. 2008; <http://image.baidu.com/search/index?tn=baiduiimage&ps=1&ct=201326592&lm=-1&cl=2&nc=1&ie=utf-8&word=FPSO>. (In Chinese)).

Operation Principle and Component

The cantilever external turret mooring system is mainly composed of a flexible riser, a liquid rotary joint, a mooring buoy, a mooring line, etc., wherein the liquid rotary joint is a core component.

Liquid rotary joints include:

1. Well flow rotary joint: The inlet end is connected to the underwater flexible hose, and the outlet end is connected with the inlet line of the FPSO production processing module to form a crude oil output passage.
2. Electric rotary joint: Power is supplied to the platform through electric rotary joints and

External Turret Single Point Mooring System, Fig. 2 Cantilever external turret single point mooring system

- power cables for use on equipment and equipment on the platform.
3. Hydraulic rotary joint: Hydraulic rotary joint provides hydraulic power control emergency shut-off valve.
 4. Emergency shut-off valve: The emergency shut-off valve is used to shut off the oil passage in an emergency state.

The mooring buoy is also a key component. Once the mooring buoy is detached, the entire mooring system fails. The pontoon has a conical structure, and a bearing assembly is arranged on the upper part of the pontoon, and the lower part of the pontoon is connected with the mooring line through the eye plate to transmit the mooring tension. The upper part is fixed to the overhanging structure by a special hydraulic locking device. Through the bearing assembly on the pontoon, under the action of environmental loads such as wind, waves, and current, the mooring center rotates or drifts. The structure of the pontoon is shown in Fig. 3. The locking device is an important component for ensuring that the pontoon does not fall off. The locking device clamps and locks the pontoon, so that the

overhanging structure is integrated with a single point. The locking device is the most critical device for a single point system. In actual production operations, the locking device must maintain sufficient preload.

Application

The advantage of the single-point mooring of the external turret is that the tanker weather mark effect is remarkable, it is easy to rotate to the orientation with the smallest environmental load (Geng-xian 2009). It does not occupy the hull storage space, and the oil tanker has high oil storage efficiency. The shortcoming is that the bow movement is the most responsive, especially in deep water mooring, the riser and turret of the external turret device are all within the range of wave slamming, which easily causes the damage of the riser and the turret. Therefore, the single point mooring device of the external turret is only suitable for medium deep waters with better marine environment.

At present, the world's largest single point mooring device for external turret is a cantilevered outreach tower designed and manufactured by FMC SOFEC. The mooring system was installed in the BIJUPIRA AND SALENA field in Brazil in August 2003. The unit can provide 18 riser and umbilical cable systems. Each mooring leg is composed of 154 mm diameter polyester cable. Under unloading conditions, the single point mooring system can withstand 360,000 tons of oil tanker and tail shuttle tanker.

Fatigue of Mooring Lines

Dongsheng Qiao
State Key Laboratory of Coastal and Offshore Engineering, Dalian University of Technology, Dalian, Liaoning, China

Definition

Fatigue of mooring lines is one of the factors that must be considered during the design of permanent mooring systems, and it is not required for mobile mooring systems. Different from the strength analysis, the maximum stress that causes fatigue damage has not yet reached the ultimate strength of material, sometimes even smaller than the yield strength. For all of the mooring line components, such as steel chain, wire, synthetic fibers, connecting hardware, etc., the fatigue analysis should be conducted in order to satisfy the fatigue design life.

Scientific Fundamentals

Historical Development

Under the long-term marine environment, the floating structures and their mooring systems are subjected to the effects of variable wind, current, and wave loads, so the alternating motion and stress/tension are caused in the mooring system. With the alternating stress/tension gradually accumulated, the cumulative fatigue damage of mooring line would occur. In recent years, many fatigue failures of mooring line in the practical projects have happened, such as during 2010–2013 where there were 15 offshore mooring line failures on the Norwegian continental shelf, according to Kvitrud (2014), and one third of them were fatigue failures, which indicates that the fatigue failure is still one of the critical failure modes of mooring system.

For the mooring chain, the first attempt to understand its fatigue behavior was conducted by a chain manufacturer Ramnäs (de Laval 1971), who used three-link samples of 2-in. oilrig chain to be tested at room temperature in dry conditions. Several companies also carried out research on the mooring chain fatigue tests, such as Shell Offshore Research (van Helvoirt 1982) who used 3-in. stud chains and connecting links to be tested under high-cycle fatigue range in artificial seawater aiming to investigate the fatigue

strength; Det Norske Veritas (DNV, Lereim 1985) who summarized the S-N curves of mooring chain links based on the 4-year research project about mooring lines; and Nippon-Kokan Kabushiki Kaisha (Asano et al. 1986) who tested samples of 40 and 44 mm of nominal diameter chain in air and water with and without cathodic protection.

For the mooring wire ropes, the first published paper related to its fatigue was conducted by Matanzo (1972), who investigated the relationship of the axial fatigue resistance of wire rope in air/seawater with the rope construction and core, as well as the effect of the applied mean load and load range, through the laboratory experiments. Lucht and Donecker (1977) also used the laboratory tests to investigate the axial tension fatigue under different field environments and deployment techniques. Hanzawa et al. (1981) presented the fatigue data for 50 mm diameter ropes with different constructions and socketing materials.

For the mooring fiber, Parsey (1982) first puts forward that the possible reason of its failure is fatigue through a SPM mooring hawsers case study. Hearle et al. (1998) divided the fiber fatigue into five effects: tensile fatigue (Bunsell and Hearle 1971; Oudet et al. 1984), hysteresis heating (Banfield and Hearle 1998), creep rupture (Hearle et al. 1993), internal abrasion (Seo et al. 1990), and axial compression (Flory 1996).

Some representative joint industry projects (JIPs) about mooring line fatigue were conducted, such as “Design Guidelines of Anchor Chains” led by Billington Osborne Moss Engineering Limited (Bolt et al. 1995); “Fiber Tethers 2000” led by Noble Denton Europe (1995); “Fatigue Testing of Large Diameter Mooring Anchor Chains” also led by Noble Denton and Associates Incorporated (Stiff et al. 1996); “Heat Build-up and Mechanical Property Behavior of Full Scale Polyester Rope” led by National Engineering Laboratory (1998); and “Mooring Integrity for Floating Offshore Installations” cooperated by 35 industry participants (Health and Safety Executive 2006, 2017).

Based on these series researches, the American Petroleum Institute (API) edited the first edition of mooring design rules including the mooring line

fatigue in 1993 (API RP 2FP1 1993) and then updated the new version in 1996, 2005, and 2008. Furthermore, API edited the mooring design rules especially for synthetic fiber ropes in 2001 (API RP 2SM 2001) and updated in 2014. Meanwhile, DNV also edited the first edition of mooring design rules in 2001 (DNV-OS-E301) and then updated the new version in 2004, 2008, 2010, and 2015.

Principles of Fatigue Analysis of Mooring Lines

In the fatigue analysis of floating structures, the most common recommended method is spectrum fatigue analysis, and typically only the wave-induced fatigue is considered. During the calculation process, the precise finite element model of floating structure should be established, and the hot spot stress position should be determined through the strength analysis of wave forces on the floating structure, and then the short-term wave state is assumed as Rayleigh distribution, so the stress of hot spot could be calculated through transfer function which will also follow Rayleigh distribution, finally the S-N curve is chosen, and the linear cumulative fatigue damage rule is used to calculate the total fatigue damage.

Different from the fatigue analysis of floating structures, the stress/tension of mooring line is calculated directly through the dynamic analysis of mooring line rather than transfer function, meanwhile all of the environmental forces induced in the mooring line tension could be considered, including the wave, current, and floater motion. As the same, the linear cumulative fatigue damage rule is also used. So, the key issues of fatigue life estimation are the fatigue resistance of mooring line components, the amplitude of cyclic stress/tension, and the loading cycle times. The specific fatigue damage analyses of mooring lines are shown as below.

Linear Accumulated Fatigue Damage Rule

The commonly used calculation method of fatigue life is the Palmgren-Miner (P-M) linear

accumulated damage hypothesis rule, which is firstly proposed by Palmgren (1924) and then popularized by Miner (1945). The P-M rule states that the fatigue damage of components or materials caused by the different stress/tension magnitudes is independent and unrelated, so the total damage is the linear superposition of fatigue damage caused by the different stress/tension magnitudes, shown as Eq. (1).

$$D = \sum_{i=1}^n D_i = \sum_{i=1}^n \frac{n_i}{N_i} \quad (1)$$

where D is the cumulative fatigue damage, and the material will be damaged when $D = 1$, n is the discrete number of stress/tension range, D_i is the fatigue damage under a different stress/tension range, n_i is the number of stress/tension cycle times in this stress/tension range, and N_i is the number of stress/tension cycle times that would lead to failure in this stress/tension range.

The design fatigue life is $1/D$, and it should be larger than the mooring system design service life multiplied a safety factor. For different mooring line components, the safety factor is different for the reason of uncertainties.

Meanwhile, there are also some other double-linear damage rules and nonlinear damage rules (Fatemi and Yang 1998), which could also be used in the fatigue design as needed.

Fatigue Resistance

The fatigue resistance gives the relationship of number of stress/tension cycle times that would lead to failure at different stress/tension range, and it should be based on a large amount of fatigue test data.

Generally, the fatigue design curves for tension-tension fatigue failure condition have been recommended by API (API RP 2SK 2008; API RP 2SM 2014) and Det Norske Veritas and Germanischer Lloyd (DNVGL OS E301 2015), and the tension-tension fatigue should be considered by all of the mooring line components. For the other types of fatigue failure, such as the out-

of-plane bending (OPB), torque and twist, and axial compression, the test data are insufficient for generating design curves.

Testing Qualification

It is also permissible to apply the actual test data for the design of a specific mooring line component rather than using design curves. During the test qualification, the test specimen, the test machine and apparatus, the test procedure, and the posttest examination should also match the requirements of corresponding standard. A linear regression analysis should be used to give the design curve, which generally located a little more than two standard deviations below the mean line, and the aim is to satisfy the prediction interval and exceedance probability. If the test is conducted in the air rather than in the seawater, a reduction of the fatigue life should also be considered.

T-N Curve

The T-N curve is recommended by API (API RP 2SK 2008; API RP 2SM 2014) and presents the number of cycles to failure for a specific mooring component as a function of constant normalized tension range, shown as Eq. (2).

$$NR^M = K \quad (2)$$

where N is the number of cycle times, R is the ratio of tension range to reference breaking strength (RBS), and M and K are the slope and intercept parameters in T-N curve, respectively, which are determined by material properties.

In Eq. (2), the stud chain links with loose stud cannot be applied, and the mean load should be included in the parameter K because it has important influence on the wire rope fatigue life.

For the common stud chain, studless chain, six/multistrand rope, spiral strand rope, and polyester rope, API has recommended the parameters value of M and K in the T-N curves.

For the other types of fiber ropes, the fatigue design should use the test data to qualify the fatigue life from the manufacturer with certification, which shall approve the test procedure.

S-N Curve

The S-N curve is recommended by DNVGL (DNVGL OS E301 2015), and it is the same approach as described in Eq. (2) with the change that the tension range R is replaced by the nominal stress range S . However, the parameters value of M and K in the S-N curve is different from T-N curve. The other considerations are the same as T-N curve.

Fatigue Damage Calculation

The fatigue life of mooring line components are estimated through comparing the long-term cyclic stress/tension with the fatigue resistance of that component. So, the long-term environment loading should be considered in the fatigue analysis, rather than the extreme environment loading used in the strength analysis.

The fatigue design under long-term environment can be represented by a number of short-term discrete sea states. Each short-term sea state has the probability of occurrence and consists of wind, wave, current parameters, and their incident directions, which could be required to calculate the mooring system motion responses. Generally, 8–12 reference directions and 10–50 reference short-term sea states provide a good representative of the long-term environment. However, the fatigue damage is sensitive to the number of short-term sea states, and the sensitivity studies should be conducted.

Annual Fatigue Damage

Based on the Eqs. (1) and (2), the fatigue damage of each short-term sea state D_i could be calculated by Eq. (3).

$$D_i = \frac{n_i}{K} E[R_i^M] \quad (3)$$

where n_i is the number of stress/tension cycle times in the sea state i , R_i is the normalized tension range using T-N curve or nominal stress using S-N curve, and $E[R_i^M]$ is the expected value.

The number of stress/tension cycle times n_i in each short-term sea state is determined by Eq. (4).

$$n_i = v_i \cdot P_i \cdot T_D \quad (4)$$

where v_i is the zero up-crossing frequency (Hertz) of the stress/tension process in the sea state i , P_i is the probability of occurrence of the sea state i , and T_D is the annual time (second).

Normalized Tension/Nominal Stress Range Calculation Method

The normalized tension/nominal stress range under the combined environmental loads could be calculated through the dynamic analysis method of mooring line or the model test method, and the static or quasi-static analysis method is not recommended. The dynamic stress/tension of mooring line could be divided into low frequency (LF) range and wave frequency (WF) range, and the fatigue damage could also be divided into LF fatigue damage and WF fatigue damage. The following four methods could be considered, in which the Methods I–III is based on the dynamic analysis of mooring line in the frequency domain and the Method IV is in the time domain.

1. Method I – Simple summation: the total fatigue damage is assumed to be the sum of LF and WF fatigue damages, which are calculated independently.

Method I is acceptable when the standard deviation stresses/tensions of WF divide the standard deviation stresses/tensions of LF is larger than 1.5 or smaller than 0.05. However, Method I may underestimate the fatigue damage when the LF and WF stresses/tensions both dominate the total stresses/tensions.

2. Method II – Combined spectrum: the total fatigue damage is calculated using the standard deviation of combined LF and WF spectrum, in which the combined LF and WF spectrum are calculated firstly.

Method II is always conservative and may significantly overestimate the fatigue damage.

3. Method III – Combined spectrum with dual narrow-banded correction factor: a correction factor is applied to the result of Method II, which is based on the two frequency bands that are present in the stress/tension process.

Method III is an improvement of Method II in order to decrease the conservative predictions, and it is suitable when the LF and WF stresses/tensions both dominate the total stresses/tensions. However, Method III will overestimate the fatigue damage when the LF stresses/tensions dominate the total stresses/tensions.

4. Method IV – Time domain cycle counting: the fatigue damage is calculated directly using a cycle counting method, such as the rainflow counting method, to obtain the fatigue load spectra from the time series of mooring line stress/tension. In other words, the histogram of stress/tension range, including the number of stress/tension cycles and the expected value of stress/tension range, could be obtained.

Method IV is the most accurate, but the analysis is relatively time-consuming.

Fracture Mechanics Approach

The fracture mechanics approach could also be used to conduct the fatigue damage estimation by modeling the crack growth under cyclic loading. The crack growth could be modeled by linear fracture mechanics based on the Paris-Erdogan equation (1963). The chain link could be treated as a round bar, and an initial surface crack is assumed to propagate at the surface, and then the stresses of chain link could be obtained through the finite element analysis (Xue et al. 2018). Meanwhile, the parameters sensitivity studies should be conducted when using the fracture mechanics approach, such as the initial crack shapes, the initial crack sizes, and the critical crack depths.

Fatigue Design Procedure

The fatigue design procedure for the mooring line is recommended as the following steps: (1) Discrete the long-term environmental into a number of short-term sea states. (2) Conduct the motion responses analysis of mooring line, and obtain the stress/tension process of mooring line. (3) Determine the fatigue design curves. (4) Calculate the

annual fatigue damage of each short-term sea state. (5) Sum of the step (4) results based on the P-M rule, and so it is the total fatigue damage. (6) Compute the fatigue life together with the step (5) and safety factor.

When selecting a fatigue design curve for the fatigue life assessment, the safety margin in all three integral parts (design curves, safety factor, and analysis method) could not be against experience and available test data.

For the polyester rope used as the free span in the mooring line, the fatigue design don't have to consider the degradation and should focus on the fatigue life of steel components because the fatigue life of polyester rope usually exceeds too much than that of steel wire or chain. However, the load-elongation properties of polyester rope have significant influence on the tension calculation of steel components.

Other Fatigue Conditions

Some of other fatigue conditions should also be considered in the fatigue design of mooring line, but not limited to the following.

OPB and Twist

The interlink rotations combined with the pretension of mooring chain could result in OPB fatigue failure at the terminations, such as the fairleads and hawse pipes (Morandini and Legerstee 2009). The wear of chain induced by the friction in the bearing must be considered, and the Archard theory of wear is suggested. The contribution to fatigue due to OPB could be solved by finite element analysis or test. The precautionary measures should be taken to avoid OPB fatigue failure, such as using a seven-pocket fairlead design, or keeping the diameter ratio of fairlead to line is large enough.

The mooring chain may cause twist under the torque effect in the adjacent link or even be inadvertently installed in a twisted condition, especially in the chain-wire/fiber-chain mooring line. The finite element analysis considering the wear or test could also be used to predict the twist fatigue damage. Meanwhile, the imposed twist

fatigue during the installation should be considered for the fiber ropes.

Axial Compression

The axial compression fatigue should be considered in an aramid rope when it is exposed to cyclic loading with a low trough tension, but it is not a concern with polyester and HMPE fiber ropes. The axial compression fatigue damage could cause strength loss, and keeping sufficient tension is benefit to prevent the axial compression fatigue damage.

Corrosion

The corrosion brings the fatigue into a corrosive environment, which could introduce mechanical degradation of a material under the combination of corrosion and cyclic loading. The simplest method of considering corrosion effect is to decrease the area of mooring line components, and the different corrosion velocities and models have been recommended. The coupled corrosion and wear effect may have significant influence on the fatigue damage estimation.

Definition

Fiber optic hydrophone is a sensor used for underwater sound measurement. Its working principle is to obtain underwater sound-related characteristics by measuring the changes in the photosensitive properties of the optical signal transmitted in the optical fiber.

Scientific Fundamentals

For the past few decades, immense research has been carried out to monitor ocean parameters

adopting trending techniques. Among them, one of the notable approaches falls in the domain of optical fiber technology. The optical fiber sensing technique has an exclusive feature of single-ended operation, that is, one end of the fiber is connected to the instrumentation node, whereas the other end is left free. The free end of the fiber is allowed to interact with the water body. This feature allows in situ examination of ocean properties rather than testing a sample of seawater in the laboratory. In a nutshell, fiber optic sensing techniques allow real-time in situ measurements providing infinite immunity to electromagnetic interference. Added conveniences in using fiber sensors are that they are less in weight, occupy a small area, and ease of availability. Hence, almost all the sensing techniques cited in this entry are applicable to ocean observation.

In general, any sensing device while deployed in the ocean should be considered for its ability to withstand high pressure and temperature. Ocean pressure increases at the rate of 145 Psi for every 100 m depth. Commercial silica fibers have the ability to withstand pressure up to 20×10^4 Psi. Also, silica fibers can endure temperature up to 900°C beyond that the core and cladding begin to drift. Since the maximum temperature of seawater is 30.5°C (as with the Red Sea, the world's warmest sea), fiber sensors can operate without any degradation in its sensing property. In seabed and polar regions, the water temperature reaches 4°C and further below. Glass fiber and photosensitive fiber can withstand cryogenic temperature up to -170°C . Abovementioned features of fiber sensors make them a befitting candidate for ocean observation and also in cryogenic temperature sensing applications (Gupta et al. 1996).

Even though fiber sensors have a lot of attractive merits, there exist few technical challenges while designing them for specific applications. In oceanography, bio-fouling and corrosion are two main issues that are to be considered while deploying any underwater module for sensing applications. To overcome these contaminants, the surface of fiber sensors should be coated with a corrosion-resistant lubricant. By doing so, the inherent sensing properties of fiber could be altered, and hence extreme care should be taken

while designing ocean optics sensors. In order to protect fiber sensors from external impurities and also to increase easy handling, the packaging is essential. Practical encapsulations for fiber sensors are made of steel, glass fiber reinforced plastic, and carbon fiber reinforced plastic. A dedicated phase control system needs to be accompanied by optical fiber sensors to maintain the finest sensitivity throughout the deployment period (Abbas et al. 2018; Wang et al. 2018).

Researchers at the Naval Physical and Oceanographic Laboratory performed the packaging of fiber optic hydrophone using polymer shell. Hydrophones are underwater acoustic signal detectors that listen and records sound signals in a water medium. Apart from sensing ocean parameters, fiber optic sensors are also involved in structural health monitoring of marine structures. Due to their tiny size and flexibility, the optical fiber could be easily inserted in composite structures. Optical strain sensors are fixed along the hull of a ship to continuously monitor stress and strain components thus ensuring the reliability of marine structures. The underlying concept of any fiber optic sensors is their ability to modulate intensity, wavelength, phase, or polarization of the optical signal concerning variations in the sensing parameter (Doyle and Staveley 2003; Vivek et al. 2017; Kumari et al. 2019).

Historical Development

In 1977, Bucaro et al. have demonstrated the feasibility of employing directly acoustic-optic interactions in an optical fiber to produce a sensitive acoustic detector for the first time. The technique utilizes the phase modulation of an optical beam in a submerged optical fiber coil by sound waves propagating in a fluid. Analysis of the results indicates that the sensitivity of this technique compares well with that of the best available hydrophone. This research has brought a revolutionary change to the development of fiber optic hydrophone technology (Bucaro et al. 1977).

In the 1980s, Interferometric fiber sensors had been widely investigated for use in a range of application areas including acoustic

pressure and magnetic fields. As with conventional electronic sensor technology, the use of arrays of sensors was often desirable for such systems, and a number of multiplexing techniques for interferometric sensors have been described (Kersey 1991).

In the 1990s, fiber optic hydrophones had been demonstrated to have better performance than conventional hydrophones, and continuing research in fiber-optic acoustic sensor heads and the associated signal modulation/demodulation system had been actively pursued. To recover the phase information from the output intensity of the fiber-optic acoustic hydrophone, different signal detection and processing schemes had been developed. These schemes included passive homodyne, active homodyne, true heterodyne, synthetic heterodyne, pseudo heterodyne, and differential delay heterodyne (Lim et al. 1999).

In recent years, fiber optic hydrophones have developed rapidly. Fiber optic sensors play an important role in the application of underwater detection systems. Especially in military applications, fiber optic hydrophone arrays have become one of the most important means for submarine detection.

Fiber Optic Sensor Technology

Figure 1 depicts a clear classification of optical sensors based on sensing methodology. The following sections focus on these sensing approaches in oceanographic applications.

Interferometric Sensing

Fiber optic interferometry is a technique that makes use of the fundamental principle of light interference for measuring changes in the physical and chemical properties of sensing medium. An interferometer could be designed using precise fiber optic components such as fibers and waveguides that control optical path. Optical fibers are preferred as the basic component to build any interferometric sensors because of their sensitivity towards elongation (change in physical length), less power consumption (in the range of micro- and milli-watts), and ability to reduce the effect of wavefront distortion caused by atmospheric turbulence. In addition to optical fibers, photonic splitters and combiners should also be accommodated to obtain a working model of Interferometric sensors.

In general, interference is defined as the superimposition of two or more light beams and interferometry is the measuring technique that evaluates phase difference between combined light beams. Variation in the sensing parameter could be estimated from the interference pattern. Based on the operating principle, interferometric sensors are classified as Fabry-Perot Interferometer (FPI), Mach-Zehnder Interferometer (MZI), and Sagnac Interferometer (SI).

FPI is an optical resonator comprising of two reflectors. The reflectors may be either planar mirrors or curved mirrors with 90% reflectivity. The distance of separation between the mirrors determines the bandwidth of resonance and wavelength resolution of FPI. Resonance bandwidth increases with the decrease in spacing between

Fiber Optic Hydrophone, Fig. 1 Classification of fiber optic hydrophone techniques (Kumari et al. 2019)

the reflectors, whereas the resolution of wavelength increases with increased spacing. Hence, a tradeoff should be made between these two factors (bandwidth and resonance) to successfully realize an FPI as a sensor.

MZI makes use of a beam splitter to split an input light into two different beams. To recognize MZI as a sensor, one of these two beams is allowed to interact with the surrounding environment whose parameters are to be sensed. The other beam is enclosed within a vacuum chamber thus behaving as a reference arm. These two beams are then combined at the output end using a beam combiner and the phase difference between them is measured. The measured phase difference is then interpreted to study the desired environmental parameter.

SI can be designed using two optical fibers with multiple wires to increase the path length to achieve high sensitivity. Like MZI, the bottom line for SI is measuring the phase difference between two beams that come out of two multi-loop optical fibers (Kumari et al. 2019).

Fiber Bragg Grating (FBG) Based Sensing

FBG can be defined as a series of in-fiber selective mirrors with specific refractive index modulation along the axial length of the fiber core. These mirror structures are inscribed inside the fiber core using femtosecond lasers or Ultra-Violet (UV) lasers. FBGs fabricated with femtosecond lasers have a central wavelength in the range of 790–850 nm and 1520–1590 nm, whereas using UV lasers FBGs could be obtained with a central wavelength ranging from 970 to 1620 nm. Germanium and boron-doped fibers are preferred for FBG fabrication as they have inherent photosensitive properties.

Grating sensors are mainly classified as a short or a long period based on the length over which grating is written. Bare FBG has a built-in sensitivity to changes in temperature and pressure. Hence to make FBG respond to a single parameter, coated FBGs were fabricated and their characteristics were analyzed. FBGs coated with metals and polymers possess excellent repeatability and sensitivity while used for sensing the

physical and chemical parameters of the ocean (Kumari et al. 2019).

Photonic Crystal Fiber (PCF) Based Sensing

PCFs are a class of fibers that are made of pure fused silica. The cladding of these fibers is formed of air holes that are distributed in a well-arranged manner around a central hole (the core). PCFs are mainly used as optical tunable devices by filling the air holes with suitable Index Matching Fluid (IMF). The Refractive index of IMF varies with respect to the surrounding temperature and electric field. This attractive feature of PCF makes it suitable for environmental sensing applications. Liquid to be filled should have a greater index of refraction compared to that of the enclosing medium. IMF can be injected inside specific air holes using a fusion splicer or by locating the tip of the air hole under a microscope (Xiao et al. 2005; Witkowska et al. 2006).

Based on the core structure, PCFs are classified into two types: hollow-core and solid-core PCF. As the name indicates, Hollow Core PCFs (HC-PCFs) have air-filled cores that are mainly used in the generation of Raman comb frequencies, high field optics, and coherent optics. HC-PCFs are also employed in discharge-based laser design and laser metrology. Liquids or gases can be filled in the core of HC-PCFs making them suitable for sensor design, the transmission of high-power optical pulses, and also in the bio-medical stream. On the other hand, Solid Core PCFs (SC-PCFs) are made of air holes surrounding a thick core of silica and work on the basis of total internal reflection (Ramsay 2008).

Surface Plasmon Resonance (SPR) Based Sensing

SPR is an optical phenomenon in which resonance of free electrons occurs on the surface of a metal-dielectric interface. The resonating wavelength varies with respect to variation in the sensing medium. Based on the system configuration, SPR sensors are classified as Prism based SPR (P-SPR) and fiber optic based SPR (FO-SPR).

Fiber Optic Hydrophone, Fig. 2 SPR based sensing methodology, (a) prism based SPR and (b) fiber optic based SPR (Sharma et al. 2007)

As the name indicates, PSPR uses a prism for reflection of resonance signal, whereas in FO-SPR the fiber itself involves the transmission of a resonant wave. The resonance of Surface Plasmon Wave (SPW) is related to the wave vector of Evanescent Wave (EW) that travels along the surface of the interfacing medium. In P-SPR, p-polarized light is incident on a metal-coated prism. EW starts to originate on the metal-prism interface. This EW component excites surface plasmon on the metal-dielectric (metal-air) layer (Fig. 2a).

In FO-SPR, the prism is replaced by an optical fiber in which cladding is chemically etched using 40% hydrofluoric acid. The cladding-less portion of the fiber is then coated with a metal (usually with gold or silver) (Fig. 2b). Along with the core-cladding interface, EW starts to propagate when input light is incident into the fiber with an optimum angle of incidence " θ " such that total internal reflection eventuates. As in P-SPR based sensors, SPW originates along with the interface of a metal and surrounding sensing layer. Any change in parameters of the sensing medium induces a shift in resonant wavelength (Sharma et al. 2007).

Even though the fundamental sensing technique is the same for both SPR methods, P-SPR uses angular interrogation, whereas FO-SPR relies on spectral interrogation techniques to obtain a calibration curve for specific sensing applications. Compared to P-SPR, FO-SPR is

preferred because of its lightweight and ease of examination. The design of the sensor head includes U-shaped and side-polished fibers (Gupta and Verma 2009).

Key Applications

A ten-element, 950 m long, vertical hydrophone array based on fiber optic data transmission has been developed primarily for studying the beam pattern from deep-diving cetaceans emitting sonar pulses, as shown in Fig. 3. The array elements have a configurable sampling rate and resolution with a maximum signal bandwidth of 90 kHz and a maximum dynamic range of 133 dB (Heerfordt et al. 2007).

Lavrov et al. (2017) have presented the results of experimental investigations of the fiber optic hydrophone array consisting of six sensors, placed in one thin sensitive cable, as shown in Fig. 4. Sensors were formed by pairs of Bragg gratings spaced 1.5 m apart and recorded in a birefringent optical fiber with the elliptical stressed coating. To form an extended sensor array, the optical fiber was additionally covered with silicone material RTV655 and protective coatings. The obtained results might be used for developing and producing long thin hydroacoustic arrays for geophysical investigations and other hydroacoustic applications.

Fiber Optic Hydrophone, Fig. 3 The concept of the fiber optic linked deep-sea hydrophone array. The enlarged section shows a canister with a hydrophone attached below it (Heerfordt et al. 2007)

Fiber Optic Hydrophone, Fig. 4 Measurement stand for fiber-optic hydroacoustic sensor array (Lavrov et al. 2017)

Fiber Optic Hydrophone, Fig. 5 Schematic configuration of the experimental setup for acoustic measurements. PD is the optical power detector, and DA is the data acquisition card (Chen et al. 2019)

Chen et al. (2019) have proposed a compact fiber-optic hydrophone and use it for acoustic wave measurements, as shown in Fig. 5. The sensor probe comprises a microresonator formed by simply tying a tapered fiber into a loop structure. After fabricating the sensor, the knot exhibits low-absorption loss underwater and, thus, the device can possibly be used as a hydrophone. The simple fabrication and small size structure of the sensor make it a good candidate for high-resolution scanning imaging.

Definition

It is with the purpose of meeting the performance specifications of optics, machinery, and the environment that optical fiber cables are made. Communication cable assemblies with one or more optical fibers in the cladding sheath of optical cables are made used as the transmission medium and can be used individually or in groups. In the structure of optical cables, a certain amount of fibers is used to form the cable core in a certain way, some of which are covered with outer sheath. Generally speaking, optical fiber cables are communication lines used to transmit optical signals (Hogari et al. 2008). Although there is certain tensile strength of optical fibers, the strength is not strong enough to withstand the practical situations of bending, twisting, and side pressure. Thus, the traditional cable which contains technology should be used, such as fitting, overlaying plastic, metal tape armoring, and so on, just like the copper cables of communication. And then, in order to make a variety of optical cables which can be used in different environments, the strength component materials are placed in the cable core, so that it can meet the laying conditions required by the projects; achieve the mechanical performances of resistance to tension, impact, bending, distortion, and so on in practical situations; and ensure the original

great transmission performance of the unchanged optical fibers (Shimizu 2008).

Scientific Fundamentals

Basic Structure

Optical cable is mainly composed of optical fiber (glass which is as thin as hair), plastic protective sheath, and plastic outer layer. It can be divided into fiber core, reinforcing steel wire, filler, and sheath. In addition, there are waterproof layer, buffer layer, insulation metal wires, and other components according to the demand. To some extent, the performance of the optical fibers has an impact on the performance of optical cables. Fiber core is the most core component in optical transmission materials of optical fibers, which can be of the glass or the plastic kind. It has a high refractive index, which is used to transmit light (Sato 1991). The thicker the fiber core is, the more the light can be transmitted through the optical fiber. The wrapping provides a low refractive index at the core interface to form the waveguide effect, forming a total reflection with the fiber core. Therefore, it can restrict the light in the optical fiber. The fiber coating/protective sheath is usually made of multilayer plastic, which has a high strength and can withstand large impact so that it can maintain the strength of the optical fiber, absorb vibration, and protect fiber core and wrapping (Li et al. 2009) (Fig. 1).

Fiber-Optic Cable, Fig. 1 The structure of optical fiber cable (http://www.orientcable.com/v_pros.asp?/35.html)

Classification

Optical cables can be classified into the following five common types according to the shape and the number of fiber cores.

Optical Cable with Center Pipe

This optical fiber is usually in the center of the center pipe, which has small cross section and is light weight. The loose pipe is located in the physical center of the optical cable, which is helpful for bending of the cable (Kurashima et al. 1991). The reason why it is usually filled with moisture-proof ointment is that it is for ensuring moisture and no longitudinal water seepage. The fiber cores of this optical cable are few, less than 12 cores.

Optical Cable with Laminated Structure

The optical cable with laminated is usually made of optical fiber with loose sheath. The structure of this kind is widely used all over the world. It is a common optical cable which is used in early optical communication and which is usually made up of 6–12 core optical fibers (Hataji 1991). The protective layer is slightly different according to the laying requirement of pipe, overhead and directly buried. All in all, the structure is complex, and there are much various steps in the manufacturing process.

Optical Cable with Framework

The optical fiber of this type locates in the frame slot. Framework materials are made of low-density polyethylene, while reinforcing cores are made of multistrand steel rope or reinforcing plastic. The number of fiber core in this optical cable is large so that it can solve the problem of transmitting congestion and shorten the connection time of optical fibers. Meanwhile, there are few wrong connections because of the optical fibers which are easy to identify (Hogari et al. 2010).

Optical Cable with Bundle of Tube

The structure of optical cable with bundle of tube style is the most reasonable for the protection of the optical fibers. There are two single steel wires in this structure which are placed in the sheath and which are used as two reinforcing cores. The

strength of this optical cable is great, especially the resistance of the lateral pressure (He et al. 2013). The number of the optical cable with bundle of tube style is flexible. In other words, the range of the number of the optical fibers is large.

Optical Cable with Tape

The optical cable with tape can hold a lot of optical fibers. The tape units of this cable are stacked into a rectangle and twisted into a cable with a certain pitch so that it can have a better bending performance.

Basic Property

Attenuation

Attenuation refers to the attenuation of optical per unit length with dB/km. As a result of the attenuation, the energy signal in optical fiber can be continuously attenuated. In order to realize long-distance optical communication and transmission, it is necessary to set up a relay station at a certain distance to enhance the attenuated signal repeatedly. Generally, attenuation is caused by two factors, and they are the internal factor and the external factor, respectively. The internal factor is mainly due to the absorption attenuation and scattering attenuation of materials. There are some additional elements in general optical glass, many of which are impurities. And most of them have electron states with low excitation energy (Kojima et al. 1982). Meanwhile, there are also some metal ions whose electron states are more easily excited than the intrinsic properties of glass. Their absorption band can appear in the visible and infrared areas of the spectrum with strong absorption attenuation. The attenuation which is caused by impurity-absorbing energy is called absorption attenuation. The scattering attenuation mainly comes from the fabrication defect and intrinsic scattering of optical fiber, which is mainly due to the fluctuation of refractive index. In refractive index, microcosmic local changes may be resulted from the random molecular structure in optical fiber materials and so do the defects and the impurity atoms. In addition, the attenuation also comes from the bending of the optical fiber and the attenuation caused by the coupling of

optical fiber when the system is constructed. Bending attenuation of optical fiber includes macro and micro bending attenuation (Hodgson et al. 2004).

Dispersion

The optical signals (pulse) with different frequency components or mode components transmit in the optical fiber at different speeds. And the signals are affected by delay distortion, which is determined by factors such as refractive index distribution of optical fiber, dispersion characteristics of optical fiber materials, pattern distribution in optical fiber, and spectral width of light source. And when a certain distance is reached, the signal distortion (pulse broadening) occurs, which is called dispersion. Dispersion can mainly be classified into material dispersion, waveguide dispersion, polarization mode dispersion, and inter-mode dispersion. Among them, inter-mode dispersion has the characteristic of the multimode fiber (Komizo et al. 2008).

Bandwidth

Bandwidth is the product of the modulation frequency and the fiber length of the maximum modulation frequency pulse that a fiber can pass through. Also, it is a comprehensive index which is used for characterizing the optical properties of multimode fiber. The narrower the bandwidth is, the wider the digital signal is spread when transmitting. And error codes are generally caused by the overlapping of code elements. In order to meet error index, the code element spacing has to be increased, leading to the decrease of the communication capacity (Toge et al. 2009). On the other hand, the extent of fiber to pulse broadening increases with the increase of transmission distance. Therefore, transmission distance cannot be too long so that it can reduce error codes.

Cutoff Wavelength

Another important parameter to measure optical cables is the cutoff wavelength, which is related to the length and the bending state of fiber. Cutoff wavelength refers to the fact that single-mode fiber usually has a certain wavelength. When the

wavelength of light transmitted is over that, the fiber only transmits lights with one mode. And when the wavelength of light transmitted is below that, the fiber can transmit light with a variety of modes (Takai and Yamauchi 2009).

Mode Field Diameter

Mode field diameter is an important performance parameter of single-mode fiber. It can be derived from the parameters of equivalent step fiber, estimate the connection and bending loss of single-mode fiber, and characterize the distribution of fundamental mode light in the core area of single-mode fiber (He et al. 2013). The light intensity of the base mode is the maximum at the axis line in the fiber core area, which decreases with the distance from the increasing axis line. Generally, mode field diameter is related to the wavelength, which increases with the increase of wavelength (Chu et al. 2004).

Active Area

The optical energy is not completely concentrated in the fiber core, part of which is transmitted in the cladding in optical fiber. Since the core diameter cannot reflect the energy distribution in the fiber, the concept of active area is put forward. When the active area is small, the density of cross section of optical fiber is large. Too excessive density will lead to the nonlinear effect, which will reduce the optical signal-to-noise ratio of optical communication system and affect the performance in the system. Therefore, the larger the active area is, the better the performance is for transmission fiber.

Numerical Aperture

Numerical aperture refers to the light that enters the end of optical fiber, which cannot be transmitted by the optical fiber completely. It is just the incident light at a certain angle which is called numerical aperture of fiber (Boscher et al. 1982).

Mechanical Property

The mechanical properties of optical fiber consist of stretching, flattening, impact, cycle bending, torsion, sheath wear, and loose casing bending. And

there are some factors that should be measured, such as tensile strength, stripping force, and dynamic fatigue parameters (Nishio et al. 1999).

Key Applications

In general, optical fiber cables are the cables that contain optical fibers. In 1976, a 144-fiber cable made by Western Electric Company was used in Atlanta by Bell Institute of America, representing that the first optical fiber communication experimental system was built. In 1980, commercial optical fiber cables made of multimode fibers began to be used for intercity truck lines and a few long-distance lines. The commercial optical fiber cables made of single-mode fiber have been used for long-distance lines since 1983. The first transoceanic fiber-optic cable between the United States, Great Britain, and France was TAT-8. It was constructed in 1988 by a consortium of companies led by AT&T Corporation, France Télécom, and British Telecom. AT&T Bell Laboratories developed the technologies used in the cable. It was able to serve the three countries with a single transatlantic crossing with the use of an innovative branching unit located underwater on the continental shelf off the coast of Great Britain. The cable lands in Tuckerton, New Jersey, USA; Widemouth Bay, England, UK; and Penmarch, France. Since then, the first subsea optical fiber cable across the Atlantic was successfully built. Until 2018, the length of the global subsea fiber-optic cables has reached 900,000 km totally, carrying more than 90% of the communication data transmission in the world (Toge and Hogari 2007).

Human society has developed into an information society so far. The amount of information exchanged is so enormous (such as sound, images, and data) that traditional means of communication can no longer meet the demands of the modern society, providing the condition of optical fiber communication widely used due to its advantages of large information capacity, good confidentiality, light weight, small volume, and long distance of non-relay segment. The applications of optical cable almost cover all industries, which

are moving to a wider and deeper level (Haro and Horche 2013).

Definition

Field Development is defined as the process by which an offshore deposit of hydrocarbon fluids is identified and developed through a structured process. While the process varies in detail between different parts of the world (influenced by differences in government processes, the nature of the hydrocarbons and the nature of the marine environment, including water depth), many of the processes are very similar while being named each with a plethora of inconsistent acronyms. Where examples are given herein, they are intended to be illustrative and not infer any preference, advantage, or disadvantage over alternates.

The process of Field Development is staged, with the highest-level summary of the staged process outlined as follows:

- **Discovery:** The hydrocarbon resource (or prospective resource) is identified.
- **Licensing:** The developer is selected through some form of competitive or structured allocation of the prospective area (permit area) as illustrated in Fig. 1.
- **Resource Appraisal Phase:** The hydrocarbon resource is evaluated and confirmed – potentially including activities such as detailed sub-surface surveying the area and/or the drilling of exploration or appraisal wells to confirm the presence and extent of the resource.
- **Project Development Phase:** A process of planning, engineering, and evaluation is undertaken in parallel with this resource quantification culminating in a Final Investment Decision (FID) on whether to proceed with the development, as illustrated in Fig. 2.
- **Construction and Pre-commissioning Phase:** The equipment, structures, and components of the Field Development are then procured, manufactured, transported, installed, and prepared for operation, including drilling and completion of the wells, subsea production system, host facilities, and export system.
- **Operational Phase:** First operation then takes place in a controlled process to commence the production phase of the Field Development.

F

Field Development, Fig. 1 Typical permit area map (NOPTA 2021)

Field Development, Fig. 2 Typical Field Development staged process (Brennan 2004)

- Following which, the field equipment and reservoir are monitored, maintained, and repaired for the producing life of the field.
- Brownfield Redevelopment Phase: Often, fields that have been producing for some time

experience a slowdown in the rate of production, which is managed through Brownfield Redevelopment where additional fields or wells are developed and brought on stream to continue production.

- **Decommissioning Phase:** After which time, when the reservoir(s) is(are) depleted, the Field Development is shut in and prepared for decommissioning.

Discovery

National governments tend to be extremely proactive in encouraging the development of their country's natural resources, including offshore hydrocarbon reserves. While these developments may generate environmental, safety, and community consequences, they often also generate significant national wealth and provide energy security through either domestic consumption of the energy produced or export revenue.

Therefore national governments often support the performance of baseline surveys of their exclusive economic territory (both marine and terrestrial) to identify prospective sites where the geology is interpreted to support the presence of (in this case) hydrocarbon fluids, as illustrated below from Geoscience Australia, which is a statutory body created and funded by the Australian Federal Government (Fig. 3).

Licensing

The awarding of locations (blocks as shown in Fig. 1) for exploration and Field Development is typically undertaken by periodic auctions by the National government. The auction typically involves commitments by the prospective Operators to undertake expenditure and work within a given timeframe on further appraisal and evaluation of the potential resources in a block, including detailed sub-bottom seismic surveys, and drilling of exploration or appraisal wells. Where Operators fail to undertake the work committed, or following identification and confirmation of resources being present if the Operator fails to progress towards Field Development (so-called fallow fields), then the license can lapse, resulting in the national government reacquiring the block. It is not uncommon for licenses for blocks to be awarded to consortia of Joint Venture (JV)

partners or for the post-award redistribution of ownership of a block to occur (so called "farm in" agreements) where an incoming participant may "pay" for their share in the future production value of the license through performance of work on the resource appraisal.

Resource Appraisal Phase

The resource appraisal phase consists of a number of distinct parallel activities to define the optimum Field Development concept, including:

- Improved definition of the hydrocarbon resource, including detailed sub-bottom seismic surveys, and drilling of exploration or appraisal wells where the type, quality, and flow properties of the reservoir can be confirmed, as illustrated in Fig. 4.
- Planning and engineering for the required wells, subsea, and surface facilities to support the production from the field. This process has different names and acronyms for the different Operators but in essence consists of a staged process (with an example shown in Fig. 2) of consideration of alternatives, selection of a preferred option, and progressive refinement of the selected concept.
- Field surveys and data acquisition, modelling, and interpretation of site conditions including geophysical, geotechnical, metocean and atmospheric aspects.
- Engineering and design activities sufficient to provide adequate definition of the preferred concept and likely costs, including supporting the key decisions on the Field Development configuration, phasing, production, processing, and export systems – commonly referred to as FEED (Front End Engineering Design).
- Management due diligence and investigation, including evaluation and analysis of environmental and community impacts from the Field Development.
- Commercial negotiations with both energy purchasers where long-term sales contracts are required to support the development

F

Field Development, Fig. 3 Typical national resources characterization map (Geoscience Australia 2014)

(typically required for LNG projects) or market modelling to determine the likely commercial performance of the Field Development where the product is anticipated to be sold into a freely traded “spot market” (such as typically the case for oil or condensate projects).

- With vendors for the supply of the equipment and services required to construct the Field Development and commence the Operational Phase.
- Commercial and management negotiations with the joint venture partners to secure agreement on the development concept, often including

Field Development, Fig. 4 Typical appraisal well flow test (TestWells 2021)

negotiations with the partners in adjacent blocks with a view to “collaborative” developments spanning across multiple licenses. This can become necessary where a resource is found to extend beyond the boundary of a single block.

These processes culminate in a proposed Field Development plan being put to the senior management or board of directors of the Operator and associated JV partners for approval, known as a “Final Investment Decision,” to either proceed with the development or recycle the concept for further evaluation, reconfiguration, and reconsideration. It is not uncommon for FID decisions to be deferred or Field Developments abandoned, depending on the global economy and level of business confidence.

Project Development Phase

Following sanctioning of the Field Development (FID), the Operators and JV partners have

committed to the expenditure of the approved budget and for the project to proceed. The initial steps are the awarding of contracts to suppliers and contractors for the longest-lead items, which either require significant resources or time to manufacture. Examples include the production facilities such as platforms (e.g., the jacket shown in Fig. 5), linepipe where long-distance export pipelines are required, or for subsea equipment such as Christmas trees where market congestion with very few qualified suppliers means that order durations significantly exceed the actual manufacturing time.

The Project Development Phase also consists of the detailed engineering design of all of the equipment and facilities for the project, with this phase characterized by the analysis of all elements of the project in a high level of detail, while there exists a very low level of tolerance for any changes which impact on other systems or elements of the development. In this phase of the project, management of change processes, quality assurance, and interface management pose some of the greatest

F

Field Development, Fig. 5 Typical fabrication site (Tamar Jacket fabrication, Deltec Group 2017)

challenges to successful delivery on-time and on-budget for the Field Development.

Construction and Pre-commissioning Phase

Careful planning of the in-field construction and commissioning phase is undertaken to ensure that the sequence of activities are performed in a safe and efficient manner, with vessels, crew and equipment mobilized, and activities completed to minimize idle time or weather downtime.

The construction sequence for different elements of the system depends on the nature of the Field Development concept selected, but each development option will result in a clear sequence of activities to ensure success of the project

development. As an example, for a conventional oil or gas platform such as the one illustrated in Fig. 6 below, the jacket must be installed and piled prior to the topsides being installed, prior to the production platform wells being drilled. The export pipelines may be installed before or after these activities, but hookup and pre-commissioning (preparing the facilities for first operation) cannot take place until each of the major elements is in place.

The pre-commissioning phase is last in this sequence and involves testing and preparing each element of the production process for introduction of hydrocarbons and commencement of production. This typically involves cleaning; pressure testing of all connections; deoxygenating of all process pipework, vessels, and pipelines; and preparation of baseline as-built documentation of the entire system ready for handover to the

Field Development, Fig. 6 Typical construction activities (Herema 2020)

operations team. The process also includes verification certification and quality assurance processes.

Operational Phase

On commencement of production, the Field Development enters into the Operational Phase. This phase is often associated with intermittent start-up, short-duration production, and process trips as any residual construction; commissioning or technical difficulties are resolved. Equipment failures or production problems are most frequently encountered either in this initial phase of operation or late in the field life once corrosion, fatigue, and other late-life integrity issues become more prevalent – these two periods of enhanced production disruption are known as the “bathtub failure curve.” The initial set of production disruptions are the most costly in terms of deferred production and net present value for the field.

Once reliable production is established, the Field Development typically enters a relatively static phase of routine production where the

hydrocarbons are produced and exported to market, with only (a) routine planned maintenance shutdowns or (b) exceptional disruptions due to severe storms where the facility has not been designed to remain permanently on station. Unlike some FPSOs which are designed to disconnect and move out of the path of tropical revolving storms (cyclones/typhoons/hurricanes), many facilities are designed to remain in production on station in even the design extreme storm event, for example, the Shell Prelude facility shown in Fig. 7 which has recently entered the operational production phase.

Brownfield Redevelopment Phase

Many Field Developments experience extended operational lives due to their redevelopment. The motivations for this can be to extend the producing life of the host facility in order to maximize the total production and therefore revenue from a facility. Motives can also be to prolong the producing life in order to postpone the considerable financial decommissioning liability. It is relatively common for Brownfield

F

Field Development, Fig. 7 Typical operational activities (Shell 2021)

Redevelopment to also coincide with transfer of ownership of the field from the original Operator responsible for the initial development, to a much smaller Operator. These smaller Operators may specialize in the operation of many such fields on a “low-cost” model of minimizing maintenance and operational overheads to extend the profitable lifespan of the Field Development. Redevelopment options commonly employed include:

- Subsea tieback of additional smaller reservoirs located in proximity to the host facility, thus increasing the total reserves accessed by the Field Development
- Reworking of the existing wells in order to enhance the production from the existing reservoir, including redrilling new wells from within the bore of existing wells
- Implementation of enhanced recovery methods, including the installation of additional waterflood wells and gas injection wells or other strategies for increasing the depletion of the existing reservoirs
- Adding subsea compression, subsea pumping, or other enhanced processing facilities to better enable efficient production from the existing

wells as the reservoir experiences late-life production phenomena such as increasing water production, greater gas/oil ratios, or decreased reservoir drive due to lowering reservoir pressure

Each of these Brownfield Redevelopment Phase actions can be considered, in some respects, as a new “Field Development” and follows most of the same steps outlined as for the original Field Development.

Decommissioning Phase

Following permanent cessation of operation/production from the Field Development, the facilities enter into the Decommissioning Phase. This phase can be characterized by a number of distinct sub-phases, which include:

- A nonoperational period while the Operator determines the preferred decommissioning plan, together with negotiation and seeking agreement and approval from statutory authorities for this decommissioning plan. Key elements involve the plans for plugging and

making safe of the wells and removal or disposal or “decommissioning in situ” of the seabed, surface and topside facilities, pipelines, subsea production, and other equipment.

- A deconstruction period where:
 - The wells are typically plugged with concrete, wellheads removed and the casing/well cut off below the mudline.
 - Removal of the surface facilities such as manifolds, platforms, topsides, risers, moorings, and floating facilities such as TLPs, FPSOs, or CALM buoys.
 - While many jurisdictions mandate removal of all installed equipment, some elements may be considered for decommissioning “in situ” such as pipelines and flowlines. The relative merits of this involve balancing potential environmental benefits from the equipment acting as a nucleating site to enhance the natural marine habitat, versus the residual impact of potential ultimate decay of the materials – which can include metal and plastic used in the original manufacture as well as some contamination from production such as mercury, normally radioactive materials and other possible pollutants.
- An indefinite residual liability period where the wells, reservoirs, and any remaining offshore equipment remain in the marine environment. While some jurisdictions transfer this residual liability to the national government, others leave the liability with the Operator in perpetuity.

Fishing Ships

Wen-Hua Chu

College of Marine Sciences, Shanghai Ocean University, Shanghai, Shanghai, China

Synonyms

Fisher; Fishing boats; Fishing vessels

Introduction

Fishing ships usually refer to production vessels that directly catch fish and other fishery resources. With the increase of voyage, the expansion of production scale, and the refinement of labor division, the traditional fishing ships, which catch fish and keep fresh on board and transport them directly back to the base port, have gradually evolved into several specialized ships engaged in fishing, processing, and transporting catches. In order to improve the efficiency of fishery production, strengthen fishery production management, make reasonable use of fishery resources, and train fishery production personnel, fishery survey ships, fishery administration ships, and fishery practice ships have appeared (Fu 1996).

Scientific Fundamentals

History

Fishing has been going on since human beings existed. It is believed that fishing ships were used as fishing tools as early as the Neolithic Age. The canoeing boat for fishing at that time was the prototype of fishing ship. With the development of productivity, the equipment of fishing ships is constantly updated, and the improvement of fishing ships also promotes the development of fishing technology.

In ancient times, the navigation and operation area of fishing ships was considerable, while the large-scale development of fishing ships in the world came after the application of steam engine

on ships. The motorization of fishing ships began with the side trawler. It was first established in Britain in 1882 and later developed in Europe, America, Asia, and other regions. Although the internal combustion engine was applied to fishing ships at the beginning of the twentieth century, the large-scale use of diesel fishing ships, replacing the steam fishing ships, was in the 1950s.

There has been an increase in fishing operations far away from the base port with the emergence of the motorization of fishing ships. Because of this, although the size of the fishing ship has increased, average accidents have also increased in view of the operation in the wind and waves. So the Germanischer Lloyd began to study the stability of fishing ships in the early twentieth century.

The processing base ship for frozen fish catches emerged in the 1930s, for the convenience of long-term offshore operations. This method of base ship fishing was first adopted by the French in the sixteenth century in the Newfoundland fishery, with the aim of extending the working time at sea. The base ship supplied the fishing ship and received the catch for salting.

If the steam engine used for fishing ships is one turning point in the fishing ship history, then another one is the emergence of the stern ramp fishing ship. In 1954, Britain built the world's first new type of stern ramp trawler (Hjue 1970), and the former Soviet Union then began the large-scale construction of it.

The development of the world's fishing ships has been affected to a certain extent with the introduction of the United Nations Convention on the Law of the Sea and the division of the 200 nautical mile exclusive economic zone. One major aspect is that the scale of fishing ships tends to go both ways. On the one hand, in order to strengthen the development and utilization of domestic offshore resources, many countries have vigorously developed small fishing ships suitable for offshore operations. On the other hand, a number of countries with developed marine fisheries have developed large- and middle-sized fishing ships, especially large ones, in order to operate in deep-sea fisheries, because they can operate in the fishery far from the base

port for a long time, adapt to the complex meteorological conditions, and be equipped with more processing equipment.

Longline fishing ships have been gradually developed with the prohibition of drifting on the high seas, because longline fishing ships are good at choosing fishing targets and protecting resources. Besides, they are effective for low resource density and are much better at improving catch quality and protecting the environment than trawlers.

Characteristics

1. Fishing ships, in order to operate at sea, must have good navigational performance, which is ensured by the hull structure and general layout adapted to the operation mode. At the same time, they must also have good fishing performance for carrying out fishing operations, increasing the catch amount and obtaining higher economic benefits (Yonghe XIE and Liping ZHAO 2004). This is mainly ensured by the reliable fishing and refrigeration machines and some fishing aid equipment (Asche et al. 2014).

There are many kinds of fishing machines, which are usually complex and with high power. The winch used by the trawler varies in tension and speed with water depth, fishing gear, ship size, and engine power. Fishing machines on the seiner may reach up to more than 20. Some seiners are equipped with three to five fishing launches to coordinate the operation. Longline fishing boats are equipped with coiling machines, payoff machines, bait hanging machines, etc. Squid fishing boat and pole fishing boat are equipped with automatic jigging machines.

Fresh preservation and processing equipment are different on various types of fishing ships. Coastal and inshore fishing trawlers mainly use ices of 0 °C or so for cold preservation (Hernández et al. 2014). Middle- and small-sized seiners mainly adopt cold seawater of −1 °C or so for refreshment (Himelbloom et al. 1994; Erikson et al. 2011). The trawlers or fishery base ship operating far from the fishing port shall adopt plate

freezing, tunnel air-blast freezing, and other low-temperature freezing (Lugasi et al. 2007). Pole fishing ships and tuna longline fishing ships mainly use cool brine, with temperature of −50–55 °C for freezing (Kamalakanth et al. 2011). In addition, catches can be processed into fillet, fish block, can, surimi, fish meal, etc. on the large- and middle-sized ocean fishing ships, which have to be equipped with a variety of fish processing machinery, such as fish washing machine, filleting machine, cutting machine, peeling machine, meat separator, fish meal machine, etc. (Fet et al. 2010; Bar 2015).

Fishing aid equipment (Asche et al. 2014), navigation, and communication devices are used to detect fish groups or assist fishing operations, such as depth fish-finder, fishing sonar, net sounder, bull trawler rangefinder, trawl warp length tensiometer, radar buoy and its receiver, etc. The modern fish-finder has been equipped with a computer to realize the function of memory, storage, analysis, and so on. Fishing sonar has developed into an electronic scanning type, which can detect fish groups in all directions and display them directly. The combination of fishing aid equipment and navigation devices forms an integrated fishing aid system.

2. Fishing ships consume oil, water, and supplies while fishing at sea, and fishing operations may have a wide and complex impact on fishing ships, which make them become operating ships with variable load and speed. Therefore, sufficient attention should be paid to the stability check.
3. The working condition of the fishing ship is extremely bad, and the operating frequency is high. Hull corrosion and equipment wear are serious, and the maintenance condition is also poor. Therefore, the design margin of the hull structure, machinery, and equipment of the fishing ship is larger.
4. Fishing ships are usually small in size, but in order to increase the catches, a large number of equipment are equipped on board. As a result, fishing ships become intensive complexes with multiple equipment.

Performance

Fishing ships, like other vessels, are engineering structures on water which must have some navigation and operation performance for navigating on water, i.e.:

Navigation Performance

1. **Buoyancy** is the ability to float on the surface of the water under certain loading conditions.
2. **Stability** is the ability to avoid tilting to dangerous angles under external forces and return to the original equilibrium position when the external force is eliminated.
3. **Insubmeribility** is the ability to maintain sufficient buoyancy and stability without sinking or capsizing when one or more cabins are damaged and flooded.
4. **Rapidity** is the ability of a ship to sail at a high speed at a certain engine power.
5. **Maneuverability** is the ability to keep the course and change course rapidly according to the intention of the pilot.
6. **Seakeeping** is the ability of a ship to maintain enough stability and structural strength when generating the swaying, slamming, green water, and stall under the action of wind and waves and other external forces and to maintain a certain speed for safe navigation.

Operation Performance

1. **Deadweight** refers to the deadweight capacity of a ship, which is usually divided into net deadweight and gross deadweight. Net deadweight refers to the quality of goods, passengers, and their luggage carried that are used for profit. Gross deadweight refers to the quality of net deadweight plus the quality of fuel, fresh water, food, fleet and their luggage, nets, and spare parts, i.e., the difference between full-load displacement and light ship displacement.
2. **Tonnage** is an indicator of the volume of the enclosed area of the ship, which is usually used as the basis for paying fees for ship inspection, berthing, water diversion, etc. It is usually divided into gross tonnage and net tonnage. Gross tonnage refers to the total volume within a ship measured in accordance with tonnage measurement specifications. Net tonnage is the remaining effective volume minus the volume

that cannot be used for profit from the gross tonnage.

3. **Speed** is the speed at which a ship sails, measured in kn.
4. **Endurance** refers to the maximum distance a ship can reach at a certain speed without adding fuel, fresh water, food, and spare parts during the voyage, measured in nautical miles.
5. **Habitability** refers to the comfort of living conditions and facilities.
6. **Robustness** means that the hull has sufficient strength and does not consume too much material to increase the weight of the hull in the navigation area.

In addition to the above, the following technical characteristic parameters are available to characterize the capability of a fishing ship to conduct fishery production:

1. **Operating radius** refers to the maximum distance from the base port to the operating fishery when the fishing ship returns to the base port after arriving at the operating fishery for fishing without adding fuel, fresh water, food, and spare parts during the voyage and can guarantee the quality of the catch.
2. **Self-sustaining capacity** refers to the maximum number of days that a fishing ship can navigate and operate at sea and ensure the quality of the catch without adding fuel, fresh water, food, and spare parts during the voyage.
3. **Catch handling capacity** refers to the number of fish that can be processed every day by ships equipped with fishing processing equipment (including freezing, fish meal, fish oil, fish paste, cans, etc.).
4. **Fishing cycle** refers to the number of days when a fishing ship is loaded with fuel, fresh water, food, and spare goods to reach the state of being able to sail again for fishing operations after arriving at the fishery for operation and returning to the base port to unload its catch. Therefore, this cycle includes the number of sailing days from the base port to the operating fishery, the number of working days including the transfer of fisheries and avoiding wind, the number of days required to return from the

fishery to the base port, and the number of days required for unloading catch and loading fuel, fresh water, food, and other spare parts.

Key Applications

According to the different tasks in fishery production, fishery ships can be divided into fishery production ships, productive fishery auxiliary ships, and nonproductive fishery auxiliary ships.

Fishery production ships refer to production ships which are mainly engaged in fishing operations directly using certain fishing gear.

1. **Trawler** is a ship that use trawl to catch fish. The trawl is a filterable fishing gear. Fish and shrimp are collected into the net in the process of trawling. The water can filter through the net, while the catch cannot pass through to achieve the purpose of catching fish. Trawlers can be divided into single boat trawler and pair trawler according to their different modes of operation. There are two types of single boat trawlers: side trawler and stern trawler. Two fishing ships tow a net together during fishing operation of the pair trawler. There is no significant difference between the single boat trawler and pair trawler, except that the trawl should be equipped with the otter board in the single boat trawler while it is not needed in the pair trawler (Fig. 1).
2. **Seiner** is a ship that uses purse seine to catch fish. The purse seine is also a kind of filterable fishing gear which is mainly used to catch pelagic fish. The rapid turning of the ship makes the net expand vertically in the water to form a circular wall around the fish for trapping them during operation. Seiners can be divided into single-boat seiner, two-boat seiner, and multi-boat seiner according to the number of ships used in the operation (Fig. 2).
3. **Angling boat** is a ship that uses fishing tackle to catch fish. Fishing tackle is a good fishing gear for catching scattered fish. It is adapted to operate in multi-reef fishery and catch large fish of good quality, which is conducive to the protection of fishery resources reproduction. Fishing tackle uses the fish's food to lure them to swallow the hook tied to the fishing line which is fitted with a seductive bait. Another way is to lay dense and sharp empty hooks on the fish migration passage for catching. Angling boats can be divided into longline fishing boat, pole fishing boat, and squid fishing boat according to the fishing gears. Longline fishing boats are fishing for large catches. Tuna is the main catch for longline fishing boat in some countries with developed marine fisheries. Pole fishing is an old fishing method. At present, skipjack is the main catch of the pole fishing boat. There is a live bait tank in the pole fishing boat on sail, which is one of the requirements different from other types of fishing

Fishing Ships, Fig. 1 Trawler. (a) Inshore trawler (<http://trawlerphotos.co.uk/gallery/showphoto.php?photo=169399&title=pino-ladra&cat=602>). (b) Ocean trawler (<http://www.sfgc.com.cn/html/yyyy/yycd/gyxtwcd/25717.html>)

ships. Squid fishing boat is a special fishing boat that uses fishing tackle to catch squid. Squid have the habit of phototaxis, which are used by squid fishing boats for light trapping (Fig. 3).

4. **Drifter** is a ship operating with drift net. Drift net is a kind of simple belt net which belongs to passive net. Its fishing principle is to connect tens to hundreds of rectangular meshes into a ribbon shape, and fish are stuck in the mesh or tied to the netting when they try to pass through. In order to protect marine fish resources, drifting on the high seas was totally prohibited on June 30, 1992. Most of the existing drifters are small fishing ships or ships operating combined with trawler or angling boat (Fig. 4).

Fishing Ships, Fig. 2 Seiner (<http://www.sfgc.com.cn/html/yyyy/yycd/jqywwcd/25708.html>)

5. **Hunting boat** is the general name of all fishing ships that use forks, darts, guns, or other tools to hunt large fish and marine mammals, such as sharks, whales, dolphins, seals, walruses, etc. hunting boat is usually small in size (except for whalers) but has a fast speed and flexible operation. It is equipped with a towing device for the catch, which is generally collected by other ships (Fig. 5).

In addition to the abovementioned fishery production ships, there are also catamaran fishing ships, mixed fishing ships, and some other fishery production ships.

Productive fishery auxiliary ships refer to ships directly engaged in auxiliary production operations.

1. **Fishery factory ship** is also known as a factory mother ship. The fishing ship is carried on it to and from the fisheries. The tasks of fishery factory boats include organizing marine fishing production; accepting and processing the catch from fishing ships; storing and transporting the processed fish product; replenishing oil, water, supplies, and other fishery materials for fishing ships and carrying out emergency maintenance, providing medical, cultural, and other services to the fleet; transferring the catch or processed fish product to the transport ship; and accepting oil, water, supplies, and other reserves (Fig. 6).

Fishing Ships, Fig. 6 Fishery factory ship (http://www.ships.lv/en/vessels/8301175-ocean_fresh.html)

2. **Light fishing ship** is an important auxiliary ship for the light seining. Its main function is to detect fish groups in fisheries and use lights to trap them. Besides, it is usually used to assist fishing ships in operation (Fig. 7).

3. **Catch carrier** is usually equipped with refrigerating equipment. Its job is to bring the catch back from the fishery to the base port. Sometimes it has to transport a certain amount of oil, water, supplies, and fishing supplies to fleets operating in fisheries (Fig. 8).

Nonproductive fishery auxiliary ships refer to ships indirectly engaged in auxiliary operations.

1. **Fishery survey ship** is an important part of the modern fishing fleet. Its mission is to investigate fishery resources, explore new fisheries, conduct experiment of fishing gear and method, and study the method of processing and keeping fresh. There are usually laboratories of resources, biology, chemistry, and processing on board, with a certain number of researchers. It is also equipped with a variety

of fishing equipment and can be engaged in trawling, seining, and angling operations (Fig. 9).

2. **Fishery training ship** is the ship for student practice. It can often carry out a variety of fishing operations, such as trawling, seining, angling, and so on. Therefore, it is equipped with a variety of fishing equipment for students to learn. It requires more cabins to meet the layout requirements of classrooms, training rooms, and living rooms, but the fish tank volume is small (Fig. 10).
3. **Fishery patrol ship** is the ship enforcing fishery laws and regulations to maintain the normal order of fishery production. Its specific tasks include patrolling the fishing grounds and supervising fishing ships to enforce the law on the reproduction of aquatic resources, supervising the implementation of fishery

agreements with the countries concerned, supervising the operation of foreign fishing ships, handling fishery disputes, and so on. It is usually required to have higher speed and better seakeeping qualities, so as to adapt to navigation in bad sea conditions. The ship is equipped with good navigation communication equipment and recording and video machines. In addition to the general sailors, there are fishery inspectors and fishery police on board (Fig. 11).

4. **Fishery rescue ship** is used to rescue fishing ships in distress, so it is required to have fast speed and good seakeeping qualities, and certain first aid equipment is also necessary (Fig. 12).
5. **Fishery supply ship** is used to supply oil, water, and supplies and to carry the rotating sailors of the fishing fleet. It is required to have larger liquid tanks and more living accommodations (Fig. 13).

Fishing Ships, Fig. 13 Fishery supply ship (<http://roll.sohu.com/20120713/n348066132.shtml>)

According to the fishing radius or sea area, fishing ships can be divided into ocean fishing ships, inshore fishing ships, and coastal fishing ships.

1. **Ocean fishing ship** refers to the ship that can fish in unlimited waters, often with a radius of several thousand nautical miles.
2. **Inshore fishing ship** refers to the ship with a radius of about 200n mile.
3. **Coastal fishing ship** refers to the ship operating within a radius of 100n mile.

According to the different fishing gear and methods, fishing ships can be divided into net fishing ships, line fishing ships, hunting ships, and ships using other fishing gear and methods.

1. **Net fishing ship** refers to the fishing ship using nets for fishing operations, such as trawlers, purse seiners, drifters, and set net fish ships.
2. **Angle fishing ship** refers to the fishing ship that uses angle gear for operations, such as longline fishing ships, pole fishing ships, squid angling ships.
3. **Hunting ship** refers to the ship that uses hunting fishing gear for operations, such as whalers.

Besides, there are some other fishing ships with different fishing gear and methods, such as light fishing ships.

According to the material of construction, fishing ships can be divided into wooden fishing ships, steel fishing ships, aluminum fishing

ships, ferro-cement fishing ships, glass fiber-reinforced plastic (GFRP) fishing ships, and polyethylene (plastic) fishing ships.

According to the propulsion methods and power equipment, fishing ships can be divided into fishing motor sailers, diesel-powered fishing ships, diesel-electric propulsion fishing ships, and steam turbine-powered fishing ships.

According to the method of fish catch preservation, fishing ships can be divided into refrigerated fishing ships, cooling seawater fishing ships, partial freezing fishing ships, freezing fishing ships, fish factory ships, and so on.

Flexible Pipes

Definition

Flexible pipes are used to transfer marine oil and gas resources, and the statement of flexible pipes is opposite to traditional steel pipes. Flexible pipes

have good stiffness and other good performance, and they are much more widely used now.

Scientific Fundamentals

Introduction

In traditional concepts, pipes are mainly divided into metal pipes and nonmetal pipes. Metal pipes have high strength and high temperature resistance, but they are vulnerable to corrosion. It has many limitations in marine oil and gas transportation (Chen 2017). Nonmetallic pipes are corrosion-resistant, light in weight, good in hydraulic performance, and easy to install, but have disadvantages, such as poor heat resistance, poor impact resistance, and large coefficient of linear expansion. With the development of modern science and technology, single-material pipes cannot meet the needs of production and social development. People use composite technology to combine pressure-resistant and non-corrosion-resistant metal materials with pressure-resistant and nonmetal materials to make flexible pipes with excellent comprehensive performance.

At present, there are three kinds of composite pipes widely used in ocean engineering: (1) flexible composite pipes; (2) nonmetal reinforced composite pipes; (3) metal reinforced composite pipes.

Flexible Composite Pipe

Flexible composite pipe is a kind of composite material pipe composed of plastic and metal. Compared with metal pipes, flexible composite pipe has the advantages of high strength, high pressure resistance, smooth surface, small friction coefficient, low heat transfer coefficient, good flexibility, long service time, good insulation performance, easy operation, convenient transportation, and good low temperature impact resistance. Therefore, the flexible pipe can allow the floating body to move in a larger range, and the pipe will not withstand large top tension. Flexible pipes are widely used in many fields, even used to transport drinking water, chemical and pharmaceutical supplies (Antal et al. 2002; Chen 2011). With the continuous development of flexible pipes, there are many kinds of flexible pipes, which can be

divided into bonded flexible composite pipes and unbonded flexible composite pipes according to the transfer mode of interlayer force.

Bonded Flexible Composite Pipes Bonded flexible composite pipe is a kind of multilayer composite structure. The layers of the pipe body are closely combined without relative slip. Generally, it consists of inner layer, middle layer, outer layer, and reinforcement layer, as shown in Fig. 1. After extrusion, it should be vulcanized to make the layers bond together so that they have a higher bonding strength (Wei et al. 2003). Bonded flexible pipes are mostly used in offshore floating or underwater oil pipes, mostly in connection with marginal oilfields and floating production systems, or in oil transportation between wharf and tanker. The corresponding standard specifications of bonded flexible composite pipes are API SPEC 17 K and ISO 13628-10. They have the following characteristics in production and use (Zhang 2011):

1. The corrosion resistance of the bonded pipe is strong because the main bearing body of the structure is embedded in the rubber matrix.
2. Under the same size and compressive capacity, the bonded pipe is lighter.
3. The production cost is low, and it has price advantage in short hose assembly.
4. Leakage is a slow leak in the pipe, which is safer than unbonded pipe.

Unbonded Flexible Composite Pipes There is no bonding effect between layers of unbonded flexible composite pipes, which allows relative

slip between layers. At the same time, the spiral bands of each reinforcing layer are also nonbonding (Zheng 2010). Usually, the reinforcing layer of the pipe is spirally wound with nonmetallic or metal materials (Chen 2005), or consists of a self-locking structure. Compared with the bonded pipe, the unbonded pipe has better performance. Its bending radius is small and curvature is large and it can produce large transverse deformation. At the same time, it can also ensure the axial tensile strength, and the ability to withstand the internal and external circumferential pressure. It can also produce in large length in production, manufacture, and application. In shallow water, unbonded pipes absorb additional stresses caused by temperature difference or vibration at both ends of the pipe through their bending deformation to protect the structural safety of the whole pipe (Feret and Boumazei 1987). Relevant design specifications for unbonded flexible composite pipes are as follows: API SPEC 17B-“Recommended Practice for Flexible Pipe” and API SPEC 17 J-“Specification for Unbonded Flexible Pipe”.

Unbonded pipe is composed of multilayer structure, including insulating layer, anti-wear layer, inner protective layer, outer protective layer, and functional reinforcement layer which plays a major role in load-bearing. According to the different materials of reinforcement layer, it can also be divided into two categories: “Metal unbonded flexible pipe” (using metal materials as reinforcement, mostly carbon steel) and “Nonmetal and unbonded flexible pipe” (using fiber reinforced resin matrix composites as reinforcement).

Metal Unbonded Flexible Pipe Figure 2 shows the typical structure of flexible metal pipes, which are carcass, internal pressure sheath, pressure

Flexible Pipes and Umbilicals,

Fig. 1 Bonded flexible composite pipe: 1 Outer layer, 2 Outer protective layer, 3 Middle layer, 4 Reinforcement layer, 5 Inner protective layer, 6 Inner layer

Flexible Pipes and Umbilicals, Fig. 2 Metal unbonded flexible pipe (Ren 2015)

armor layer, anti-wear layer, tensile armor layer, insulation layer, outer sheath from inside to outside. They have friction and allow relative slip (Wellstream 2010).

Carcass: A self-locking metal structure with S-shaped cross-section and gaps between layers is used in the innermost layer of pipe. When the pipe is subjected to external pressure or impact load, it can resist the collapse of the lining or the whole pipe and prevent the collapse of the structure. Sometimes it can be placed on the outer layer to protect the outer layer of the pipe. Carbon steel, stainless steel, nickel-based alloy, and other materials are usually used.

Internal pressure sheath: The material is a polymer, which prevents the fluid from leaking into the external structure and guarantees the integrity of the internal fluid. This layer has obvious creep effect.

Pressure armor layer: Self-locking structure or rectangular cross-section spiral winding structure can be used. The winding angle is close to 90° degrees. This layer can enhance the internal and external pressure bearing capacity of pipe and resist mechanical impact load. It has many structural forms (American Petroleum Institute 2012a). Carbon steel is selected as the material and carbon content is determined according to the design

requirements. Sometimes aluminum alloy can be selected (Out and Morgen 1997).

Anti-wear layer: Polymer material located between two metal structural layers which is used to reduce the friction damage between adjacent reinforcement layers and improve the fatigue life of pipes. Generally, the stiffness is not considered. Common materials are high density polyethylene (HDPE), cross-linked polyethylene (XLPE), medium density polyethylene (MDPE), nylon 11 (PA-11), polyvinylidene fluoride (PVDF).

Tensile armor layer: It is made of a pair of flat steel spirals with opposite winding angles. The winding angles are usually between 20 and 55 and mainly bear the effects of tension, torque, and internal and external pressure. The material of this layer is the same as the pressure armor layer. The type of carbon steel can be selected reasonably according to the design requirements. Sometimes, aluminum alloy can also be selected (American Petroleum Institute 2012b).

Insulation layer: This layer is located between the tensile layer and the outer layer. It is used to improve the thermal insulation and thermal insulation performance of pipes. PP/PVC/PU insulation material is used.

Outer sheath: Polymer material is used as the outermost structure of the pipe, which isolates the

internal structure from the external environment, protects the pipe from corrosion and wear by sea water, and keeps the flat strip of the tensile layer spirally wound and formed without dislocation. The materials used are usually high density polyethylene (HDPE) and nylon 11 (PA-11).

Nonmetal Unbonded Flexible Pipe Nonmetallic unbonded flexible pipes are reinforced with fiber-reinforced composite. Compared with metal flexible pipes, this new type of pipe does not have carcass, and both tensile and compressive layers are composite, so the whole pipe is nonmetallic materials.

Figure 3 is a typical structure of a flexible nonmetallic composite pipe. From the inside to the outside, they are: Liner Extrusion, Anti-Extrusion Layer, Hoop Reinforcement, Anti-wear Layer, Membrane Extrusion, Tensile Reinforcement, Anti-wear Layer, Outer Sheath.

Liner Extrusion: The polymer extruded by the extruder can prevent the fluid leakage inside the pipe and ensure the integrity of the internal fluid. It has good wear resistance and smooth inner wall, which is more conducive to the transportation of crude oil. The performance of this layer is mainly affected by temperature and internal flow material. HDPE, XLPE, PA-11, PVDF, PE-RT are often used.

Hoop Reinforcement: It is made of several flat strips spirally wound, and the winding angle is

close to 90° . The flat strip is a composite laminate with rectangular cross section. Friction between the flat strip and the flat strip is allowed and relative slip is allowed. Glass fiber-reinforced polymer, carbon fiber-reinforced polymer, and aramid fiber-reinforced polymer are commonly used in flat strip (American Society for Testing and Materials 2007).

Anti-wear Layer: The main function is to reduce the wear between layers, prevent the leakage of internal gas, insulate, and keep warm.

Tensile Reinforcement: The two layers appear in pairs, and the helical angles of the two layers are positive and negative. The material of hoop reinforcement layer is also spirally wound by composite flat strip. The winding angle is generally between 25 and 55 with rectangular section shape. Friction and relative slip are allowed. If necessary, more pairs of tension reinforcement layers can be added to improve the mechanical properties of pipes.

The advantages of nonmetallic flexible pipes are as follows:

1. Light weight and high specific strength, it is 25–50% lighter than metal reinforced flexible pipe, which is more suitable for deep and ultra-deep water environment (DNV 2010).
2. Nonmetallic composite laminates have better fatigue resistance and structural integrity.

Flexible Pipes and Umbilicals,

Fig. 3 Nonmetallic composite pipe (Zhang, 2014)

3. The installation process is more convenient, the installation and deployment cost is lower and more economical.
4. Good resistance to high temperature and corrosion and the fatigue life is longer.
5. Good wear resistance, the inner wall is smooth which improves the fluidity of crude oil transportation.
6. The whole pipe structure is made of nonmetallic materials with low thermal conductivity and good thermal insulation performance.

Nonmetallic Reinforced Composite Pipe

Nonmetallic reinforced composite pipe has the advantages of light weight, high specific strength, low hydraulic friction, long service life, and convenient installation. The reinforcing materials used in nonmetallic reinforced composite pipes are mainly glass fiber, carbon fiber, aramid fiber, ultra-high molecular weight polyethylene fiber, and so on (Lu 2005). Compared with glass fibers, carbon fibers and other fibers are expensive and costly to process. In fact, up to 98% of the nonmetallic matrix reinforced composite pipes use glass fibers as reinforcing materials, only 2% use carbon fibers, aramid fibers, ultra-high molecular weight polyethylene fibers, and other fibers (Wang and Jiang. 2003). Therefore, the glass fiber-reinforced composite pipes are only introduced as follows.

Fiberglass-reinforced plastic pipe (GFRP or FRP pipe) is a kind of flexible composite pipe (resin, fiber, sand, etc.) which has been widely used at home and abroad. Glass fiber-reinforced continuous plastic composite pipe is a kind of multilayer structure and high performance

composite pipe. Its inner layer is a medium conveying layer made of special polymer. It not only has the characteristics of corrosion resistance and wear resistance but also has a hydrophilic material on the surface. When transporting waxy crude oil, it can effectively prevent wax condensation in the pipe. The middle layer is reinforced by high performance resin glass fiber composite material. The layer winds at different angles on the outer side of the inner layer, which makes the pipes have higher pressure bearing capacity. The whole pipe is wrapped by polymer materials, which can effectively prevent the damp, thermal, light, and mechanical damage of the external environment, as shown in Fig. 4 (Xia et al. 2013).

Compared with traditional pipes, FRP composite pipes have the following advantages:

1. Good corrosion resistance and dielectric properties
2. Strong elasticity and toughness, creep resistance and surface scratch resistance
3. Easy to design
4. Good thermal performance, low coefficient of expansion, strong thermal insulation and heat preservation capability

Metal-Reinforced Composite Pipe

According to manufacturing process, metal-reinforced composite pipes can be divided into steel wire wound reinforced plastic composite pipes (PSP pipes), steel wire spot welded into mesh reinforced plastic composite pipes (SPE pipes), and porous steel strip plastic composite pipes (PSSCP pipes).

Flexible Pipes and Umbilicals,

Fig. 4 Fiberglass-reinforced plastic pipe

Steel Wire Wound Reinforced Plastic Composite Pipe Steel wire wound reinforced plastic composite pipe (PSP) is a steel-plastic composite structure, which is based on thermoplastic-high density polyethylene (HDPE) and reinforced by reticulated skeleton formed by staggered winding of high strength steel wire. The steel wire and HDPE are bonded by high performance resin, as shown in Fig. 5 (Zhao 2013).

The unique structure of PSP not only integrates the advantages of high strength of steel pipe and corrosion resistance of plastic pipe but also overcomes the defects of metal plate skeleton reinforced plastic composite pipe such as easy delamination. PSP has the advantages of high production efficiency, strong structural design, strong bearing capacity, good corrosion resistance, good wear resistance, high cost performance, light weight, and convenient transportation and installation. It has been widely used in municipal engineering, civil construction, pharmaceutical and chemical industry, agriculture, and coal chemical industry, and has produced remarkable social benefits and huge economic benefits (Zheng et al. 2012).

Steel Wire Spot Welded into Mesh Reinforced Plastic Composite Pipe Steel wire spot welded into mesh reinforced plastic composite pipes (SPE

pipe) is a new type of double-sided anticorrosive pressure pipe formed by continuous film drawing on production line, which is based on high-quality low-carbon steel wire as reinforcing phase and high-density polyethylene (HDPE) as matrix. Spot welded steel wire is synchronized with plastic extrusion filling, as shown in Fig. 6 (Zhao 2013).

The tubular wire mesh in SPE pipe is made of warp wire and weft wire by winding and welding. The warp wire is parallel to the center line of SPE pipe, while the weft wire is wound around the outer layer of the warp wire. The diameters of warp and weft wires are 2–4 mm low carbon steel wires. In the production of SPE pipes, steel wires are laid along the axis of the pipe with an interval of 8 mm and wound at an interval of 8–12 mm along the outer ring of the steel wires. Then the steel wires are spot welded into a mesh structure, filled with high density polyethylene on both sides of the mesh structure, and wrapped in the middle of the mesh structure to form a stable steel skeleton polyethylene structure.

Due to the complex winding process, slow production speed and thicker pipe wall structure of wire spot welding reinforced composite pipe, the proportion of composite pipe is large, the cost is high, and the transportation and installation are

Flexible Pipes and Umbilicals, Fig. 5 Steel wire wound reinforced plastic composite pipe: (a) The overall structure (b) Reinforcement structure

F

Flexible Pipes and Umbilicals, Fig. 6 Steel wire spot welded into mesh reinforced plastic composite pipe: (a) The overall structure (b) Reinforcement structure

Flexible Pipes and Umbilicals, Fig. 7 Porous steel strip plastic composite pipe

very inconvenient. Therefore, its application field is greatly limited (Wang et al. 2017).

Porous Steel Strip Plastic Composite Pipe Porous steel strip plastic composite pipes (PSSCP) are made of cold-rolled steel strip and thermoplastic high-density polyethylene, and the porous thin-walled pipe formed by hydrogen arc butt welding is used as a reinforcement. It is a new composite pressure pipe with a double-sided composite thermoplastic in the outer and inner layers, as shown in Fig. 7.

It is made of cold-rolled steel strip after punching, coiled, and welded into mesh steel pipe.

The inner and outer layers are made of thermoplastic resin and continuously compounded by extrusion. By hot melting, the inner and outer plastic layers can be contained through thin steel strip mesh, which can avoid the separation and peeling of plastics and metals, solve the problem of insufficient strength and stiffness of pure plastic pipes, and control the linear expansion coefficient of plastics. It integrates the advantages of steel pipe and HDPE. The pipe is smooth and hard. It can be used in the environment of -40 – 120 °C. It can resist corrosion, pressure, and abrasion on both sides. It has been widely used in petroleum, chemical, metallurgy, construction, and environmental protection (Tian et al. 2008).

Umbilicals

Definition

Umbilical is a key component of subsea control system, which connects the upper facilities and subsea production system (Fig. 8), and transmits hydraulic pressure, electric, control signals, and chemicals between them.

Introduction

Subsea umbilical is installed between the host facility and the subsea facility. In general, the umbilical includes a catenary riser (dynamic segment) transitioning into a static segment along the seabed to the umbilical termination assembly (UTA) at the subsea facility. For shorter lengths, the segments may be identical. The umbilical pull-head will include a split flange (or other) assembly for hang-off of the umbilical at the host facility. A bend stiffener or limiter may be installed at the top of the catenary riser and at the UTA (Yong Bai and Qing Bai 2012).

General requirements for the umbilical system include:

- Electrical power, control, and data signals should, as a base case, be contained on the same pair of conductors.
- Super duplex steel tubes should be used. (Other materials can be considered but substantial documentation should be required to guarantee their applicability.)

- The umbilical is fabricated in one continuous length.
- The umbilical system is designed without any planned change-out over the design life.

Development History of Umbilical

Umbilical has been used in oceanographic engineering for nearly 60 years. The earliest umbilical appeared in the 1960s. It was used in a 16 m-deep underwater well built by Shell in the Gulf of Mexico in 1961. The umbilical is a direct hydraulic type, which is composed of many hydraulic pipes, each of which is connected with the corresponding tree valve, and the whole cable has a large cross-sectional area (Yijimei 2014).

In the 1970s, due to the wide application of hydraulic directional valve and integrated circuit technology, electrohydraulic composite control system appeared, which greatly reduced the cross-sectional area of umbilical. By this time, umbilical was no longer only composed of pipes, but also power cables and data transmission lines.

The early umbilical pipes used thermoplastic hosepipes (Fig. 9). It was not until 1982 that Sandvik company first replaced thermoplastic hosepipes with steel pipes and successfully applied them in the Frigg oil and gas field development in northeast Norway. This umbilical is 57 km long and is used for remote hydraulic control and methanol injection. Unfortunately, in the next few years, the development of steel umbilical has not got enough attention.

Flexible Pipes and Umbilicals,
Fig. 8 Umbilical

However, in the late 1980s, as the depth of water increased, some problems of the hosepipes gradually emerged, so it is getting more and more

Flexible Pipes and Umbilicals, Fig. 9 Hose umbilical

limited. Leakage occurred at the connection and hydraulic fittings, methanol leakage occurred in the hosepipes, the hosepipes was crushed in the deep-water environment, and the cable and connector take in water problem troubled the whole umbilical industry. As a result, since the 1990s, steel pipe and fiber optic umbilical have received increasing attention and have been increasingly used in offshore oil development.

The main materials for steel pipe are carbon steel, duplex stainless steel, super duplex stainless steel, etc. (Fig. 10). However, the price of umbilical with metal tube is high, and economic factors should be taken into account when choosing it.

In the twenty-first century, with the increase of the depth of water, it is necessary to supply high-voltage power to the deep-water subsea production system. Therefore, the requirements for the voltage level of the umbilical have been raised. In 2005, Nexans began developing and producing the world's first umbilical with a high voltage (24 kV) cable for BP's two subsea recovery Wells in the Gulf of Mexico at a depth of 988 m; it is 26 km long. Since then, high-voltage umbilical has been used in offshore deep-water oilfield development.

Flexible Pipes and Umbilicals, Fig. 10 Steel pipe umbilical

At present, umbilical laying depth is increasing, such as the TIGER oil field in the Gulf of Mexico began to install the laying of steel pipe umbilical in 2009, the water depth reached 2743 m.

The laying length of umbilical is also increasing, ranging from 500 m to 130 km. In 2005, Nexans produced steel pipe umbilical for the offshore gas field of Snohvit, the state oil company of Norway, reaching 143 km. The single longest thermoplastic umbilical is 31 km, produced by the Newcastle Facility and used in the Exxon Mobil Arthur project (Guo et al. 2016; Sun et al. 2011).

Types of Umbilical

According to the actual needs of oil and gas field engineering, the reserved facilities, external pipe diameter conditions, and user requirements, there are great differences in the types of units and the number of units in umbilical. Therefore, umbilical products are typical individual customized products.

According to the types of internal units, umbilical can be divided into cable umbilical, hydraulic umbilical, optical fiber umbilical, electro-optical composite umbilical, hydraulic fiber composite umbilical, electro-optical composite umbilical,

electro-optical composite umbilical, electro-optical liquid composite umbilical, and integrated application umbilical (in addition to the photoelectric liquid unit, it also contains oil and gas channels) (Collins 2008).

The umbilical including pipe units can also be divided into steel pipe umbilical and hosepipe umbilical according to the types of pipe units.

Moreover, umbilical can be classified into unarmored umbilical and armored umbilical according to whether or not they contain armored layers. According to different armored materials, it can be divided into metal armored umbilical and nonmetal armored umbilical. The armored umbilical can be divided into single, double, and multi-layer armored umbilical according to the number of armored layers.

According to different working conditions of umbilical, it can be divided into static umbilical and dynamic umbilical. The following is a brief introduction of common umbilical in the world (Guo et al. 2016).

Single-Layer Armored Optoelectronic-Hydraulic Composite Steel Tube Umbilical

Figure 11 shows a typical cross section of single-layer armored optoelectronic-hydraulic

Flexible Pipes and Umbilicals,

Fig. 11 Typical cross section of single-layer armored optoelectronic-hydraulic composite steel tube umbilical

composite steel tube umbilical. The umbilical can deliver power, control, electrical and optical signals, hydraulic power, and chemical agents simultaneously.

Two-Layer Armored Optoelectronic-Hydraulic Composite Steel Tube Umbilical

Figure 12 shows a typical cross section of two-layer armored optoelectronic-hydraulic composite steel tube umbilical. Its function is the same as that of single-layer armored optoelectronic-hydraulic composite steel tube umbilical; the difference is that the umbilical is armored with two layers of flat steel wire, only one layer of outer sheath and inner lining. This type of umbilical is also suitable for subsea production systems with electrohydraulic composite control.

Electrohydraulic Composite Hose Umbilical

Electrohydraulic composite hose umbilical is suitable for subsea production systems with electrohydraulic composite control (Fig. 13). Because of the permeability and self-expansion of the hose-pipe, it is suitable for the working condition with short control distance and low demand of hydraulic response.

It uses five layers of rounding steel wire for armoring. Armoring can bear the tensile load, increase the stability of the seabed, and protect the internal structure of the cable body.

Electrohydraulic Composite Soft Steel Pipe Umbilical

Similar to the electrohydraulic composite hose-pipe umbilical, it is suitable for the subsea production system with electrohydraulic composite control mode. The difference is that both hosepipe and steel pipe are used in the pipe unit (Fig. 14).

Carbon Fiber Umbilical

To reduce the weight of the umbilical cable, carbon fiber rods can be added. It has the same stiffness as steel and has a weight loss of 80%. This rod is made of 48 K carbon fiber and vinyl ester resin. As shown in Fig. 15, the carbon fiber pultrusion rods are arranged in the cavity of the outer circumference and the plastic profile inside the umbilical structure. Stainless steel tubes are distributed in the extruded plastic profiles, and the carbon fiber pultrusion rods are placed in the cable production at the same helix angle like other parts (Yu and Su 2008).

Flexible Pipes and Umbilicals,

Flexible Pipes and Umbilicals, Fig. 13 Cross section of electrohydraulic composite hose umbilical

Flexible Pipes and Umbilicals, Fig. 14 Cross section of electrohydraulic composite soft steel pipe umbilical

Umbilical Components and Unit

Umbilical vary widely in structure, it has different structures for different environments, and there is almost no uniform standard and style of it. Generally speaking, it is mainly composed of cables (power

cable, signal cable, or power signal cable), optical cables (single-mode or multi-mode), hydraulic or chemical pipe (steel pipe or hosepipe), polymer sheath, carbon fiber rod or armored steel wire and filler (VSolovev et al. 2017).

Flexible Pipes and Umbilicals,**Fig. 15** Carbon fiber umbilical

F

A subsea umbilical consists of electrical cables, fiber optic cables, steel tubes, and thermoplastic hoses. It may also include two or three of these four components for executing specific functions. The umbilical components are designed and manufactured to meet the umbilical functional and technical requirements. Proper materials are chosen to manufacture the components, and verification and acceptance tests are done to demonstrate the conformance to the component functional and technical requirements (ISO 13628-5 2009).

Cable is mainly used for the transmission of power and control electricity, and can also be used for signal transmission when electric communication is adopted. Fiber optic cable is mainly used for transmitting various signals, and in special circumstances, it can also be used for monitoring the status of umbilical itself. Various pipes (including steel pipes and hosepipes) are used to transmit hydraulic fluids, chemicals, and oil gas. Polymer sheath is generally wrapped in cables and various types of pipes outside, which play a role in insulation and protection. Carbon fiber rod or armored steel wire is generally arranged around

the umbilical, which can increase the axial stiffness and strength of the cable body, as well as the mass per unit length of the cable body, which enhances the submarine stability of the umbilical. Fillers are used to fill voids and to fix the relative positions of each component of the cable body (Guo et al. 2016).

Electrical Cable

Electrical cable consists of conductor, insulation, sheath, etc. Some cable units are also shielded and armored. Cables are divided into power cables and signal cables. The insulating layer provides dielectric strength and electrical insulation. Electrical cable is equipped with jacket, which can protect the cable unit, round the cable, and adjust the size and weight. The shielding layer is mainly used to shield the magnetic field. Armor mainly plays a strengthening role.

Fiber Optic Cable

Fiber optic cables are capable of continuous operation when immersed in a seawater environment. The fiber type is of either single-mode or multi-mode design. The design is as given in the

manufacturer's/supplier's specifications. Individual fiber identification is by means of fiber coloring. The fibers are contained within a package that prevents water and minimizes hydrogen contact with each fiber. The carrier package for mechanical protection and its contents are designed to block water ingress in the event that the fiber optic cable in the umbilical is severed.

Pipe Unit

Pipe material is steel pipe or plastic hosepipe. The umbilical used in the deep sea are mostly made of steel tubes, which have better resistance to internal and external pressure and permeability than plastic hoses. Most steel pipes are lined with plastic, which plays a role of cushioning and reducing wear between steel pipes and other components.

Filler

The main functions of fillers are as follows: It makes the umbilical rounded and easy to be processed in the following process, and it is also conducive to strengthening external components to play the role in improving the ability of the umbilical to resist lateral pressure and reducing the friction between functional components and layers. Improve the stability of umbilical structure. When water resistance is required, fill the water resistance material and wrap it around the water resistance belt.

Armor Layer

According to the purpose, environment, and state of use of umbilical, different armored forms can be selected, such as single layer round wire, double or four layered round wire, and double or four layered flat wire. The steel wire mainly plays a strengthening role, providing tensile, torsional, and compressive protection for the umbilical, and at the same time, the steel wire also plays a shielding role, mainly shielding the magnetic field. The armoring method of single layer round steel wire is rarely used, and it is mainly used in places with low tensile requirements such as shallow sea or rivers. The advantages of this armoring method are light weight and softness, and the

disadvantages are poor tensile strength and lateral compression resistance, and the cable is easy to twist when being pulled. In the double round steel wire, the winding direction of the double round steel wire is opposite, so the cable is not easy to twist. Compared with double round steel wire, flat wire has the advantages of reducing the external diameter of the cable and increasing the lateral compression resistance of umbilical cord cable. The disadvantage of the cable is hard, bending performance is poor. The combination of flat steel wire and round steel wire has the advantages of excellent tensile strength and lateral compression resistance, but it has a heavy weight and is suitable for the environment susceptible to high mechanical external forces.

Sheath

The sheath is divided into inner sheath and outer sheath. The function of the inner sheath is to provide mechanical buffering, reduce friction, prevent corrosion, and stabilize the cable structure. The outer sheath is the last line of defense for the umbilical. In addition to playing the role of inner sheath, it also has high anticorrosion performance, ultraviolet resistance, and seawater resistance. Some umbilical cord cables require an outer sheath that is resistant to mold and marine life (Gao et al. 2011; Guo et al. 2011).

Bending strength of sea ice

Definition

Flexural strength of sea ice is the maximum bending stress that the sea-ice material can take. This definition is drawn from the traditional material mechanics. Once the sea-ice strength is surpassed, the failure and fracture of sea-ice plate are followed. The flexural strength is closely connected with many natural phenomenon and engineering properties of sea ice. For example, the breakup, rafting, and ridge-building are often observed in polar area and seasonal ice-covered region, when the ice covers are under the actions of wave, current, and wind. In the cold region, the jacket platform with ice-breaking

cones, artificial island, slope protection, and ice breaker suffer from the collision of the ice cover. These situations generally cause the bending failure mode of sea ice, and the ice loads of the structures are subsequently determined by the flexural strength.

In essence, the flexural strength of sea ice is induced by the momentum parallel to the ice cover. The momentum generally causes the longitudinal stresses, compressive, and tensile, which distribute linearly with perpendicular distance from the neutral axis in a pure and homogeneous elastic material. Note that the fissure appears at the surface with the zone of critical stress to be very thin, and the fissure propagates in a stress gradient. As we know that sea ice is a complex material with multiphase, anisotropy and not pure elasticity, the effective moduli for tension and compression are not equal, when sea ice takes the bending momentum. Therefore, the sea-ice mechanical properties evidently perform inhomogeneous. Unlikely to the classic material mechanics, the flexural strength of sea ice does not equal to the uniaxial tensile strength.

Flexural Strength of Sea Ice, Fig. 1 Three types of flexural strength tests for sea ice: (a) cantilever beam, (b) three-point beam, and (c) four-point beam

Scientific Fundamentals

Test Types

In general, the flexural strength of sea ice is acquired through the tests in laboratory or in situ. According to the loading types, there exist three test patterns: three-point beam test, four-point beam test, and cantilever beam test, as shown in Fig. 1. Cantilever beam test can only be carried out in situ, and the other two are applicable both in situ and in laboratory.

Cantilever beam test is a full-scale measurement of the strength and the load is applied at the free end of sea-ice sample until the sample breaks at the base of the beam. Three-point beam test and four-point beam test are performed based on the cubical samples cut off from the ice cover, and the loading points are on the center point and middle two of the quantile points, respectively. Cantilever beam test is much better than the other two on measuring the real strength condition of sea ice, because the sea-ice state is maximally preserved in situ without significant movement (Timco and

Weeks 2010). Specifically, cantilever beam test facilitates a relatively easy way to perform on a large beam and can keep the natural temperature gradient in the ice sheet. However, cantilever beam test is highly consuming on many aspects such as time and labor, so it is hard to guarantee enough number of the test for the mechanical property studies of sea ice. Besides, the result of the test is influenced by the variation of physical properties with ice depth, which is brought about by the ice growth history. Stress concentration at the corners of the beam root is another concern for the test. The root of the cantilever may be not rigid enough, especially when the beam is much wider with reference to its depth. The stress concentration sometimes takes place at the corners of the beam root, which could introduce extra error for the measurement of the flexural strength and even fail the measurement.

Otherwise, the three- and four-point beam test is most widely used because of its controllability and feasibility, and its failure position is anticipated much easier than the four-point beam test.

More often, the three-point beam test is preferred to be performed in a laboratory on smaller samples of ice cut from the ice cover. Therefore, most of the studies on the relationship between the sea-ice flexural strength and its influencing factors are based on the three-point beam test. However, the broken location of the three-point beam test is often at the midpoint of the beam, where takes the maximum moment. As a result, the failing location may not be the weakest of the sea-ice sample.

Whereas, four-point bending tests preserve a section of the beam, where the moment is constant and the shear stress is zero. This distribution is able to guarantee the failure happens at the weakest point of the sea-ice sample. Therefore, the four-point test is highly recommended for sea ice, although it is a little more complex than the three-point test.

Stress concentration is another concern to carry out three- and four-point beam test. During the test, the local indentation effects sometimes happen at the loading and supporting points. This has a negative effect on the accuracy of the flexural strength. To avoid stress concentration or local indentations at these points, the test apparatus is suggested to have cylinder supports, which should have enough stiffness comparing with sea-ice sample (ITTC 2014).

The flexural strength of sea ice is not considered as a basic material property. The distribution of the stress field is not uniform inside the sample for the test of flexural strength. The flexural strength of sea ice is more complex than the classic mechanics, and there needs to be extra assumptions to explain the test results. However, because it is a necessary parameter for numerical simulation and ice engineering projects, the flexural strength of sea ice is widely measured.

Influencing Factors of Flexural Strength

Many physical properties of sea ice influence the flexural strength such as salinity, porosity, and temperature. As a deduced parameter from salinity and temperature of sea ice, the brine volume is widely adopted to reflect the physical properties

of sea ice, when the relationship between flexural strength and physical properties of sea ice is investigated. Sea ice is also a rate-dependent material, thus many researchers arguably identify stress rate as another parameter to influence the flexural strength of sea ice. In addition, the scale effect of the flexural strength is observable, so the strength deriving from the small scale test cannot be directly applied to the sea-ice process of the large scale.

Sea-ice temperature is a key element to determine the flexural strength. On microscale, the lower sea-ice temperature is, the denser ice crystal conglomerates. As is embedded on the macro-scale, the flexural strength becomes stronger. Many studies suggest that sea-ice flexural strength is approximately a linear function of its temperature. The flexural strength increases with the decrease of the sea-ice temperature. Contrarily, sea-ice salinity sustains a positive relationship with the flexural strength. The higher salinity of sea ice prone to make more porosity inside of the sea ice, the distribution of these defaults inside the sea ice lower the flexural strength. However, the significance of the linear relationship between the flexural strength and the sea-ice salinity is low, so the influence of the salinity on the flexural strength is more complex. Alternatively, the sea-ice brine volume is computed from the sea-ice temperature and salinity, and it thus can combine these two influencing factor into one variable by (Frankenstein and Garner 1967):

$$v_b = S_i \left(\frac{49.185}{|T_i|} + 0.532 \right)$$

where v_b , S_i , and T_i denotes brine volume, salinity, and temperature of sea ice. This equation is validated only when the ice temperature is $-22.9^\circ\text{C} \leq T_i \leq -0.5^\circ\text{C}$. Therefore, the brine volume tend to be selected to probe into the influence of sea-ice physical properties on the flexural strength.

Many flexural strength tests have been carried out to investigate the relationship between the brine volume and the flexural strength. Most of the researchers reported that the flexural strength of sea ice has a negative exponential relationship

to square root of brine volume. The others concluded that the flexural strength of sea ice is a linear function of square root of brine volume. Although the form of the equation is given, the fitting parameters are a little different from different researchers and different experimental sites. Timco and O'Brien (1994) combined 2500 reported measurements of the flexural strength of freshwater ice (1556 beams) and first-year sea ice (939 beams), as shown Fig. 2. They gave the exponential correlation between the flexural strength and the square root of brine volume as:

$$\sigma_f = ae^{-c\sqrt{v_b}}$$

where σ_f and v_b denotes flexural strength and brine volume of sea ice, respectively. a and c are the parameters through the fitting line.

This equation is most representative to calculate sea-ice flexural strength just based on the temperature and salinity of sea ice. Basically, its data comes from a large number of researchers and thus significantly compromises the fitting parameters of a variety of geographic locations, in both polar and seasonal ice-covered region. It is worthwhile to point out that there may be remarkable difference for some certain regions from the fitting parameters (as shown by Fig. 3), but the exponential correlation has been confirmed to be

effective to fit the flexural strength and brine volume of sea ice (Ji et al. 2011).

The dependence of the flexural strength on strain (stress) rate is seldom studied and remained as a debatable question (Timco and Weeks 2010; Timco and O'Brien 1994). The dependence on stress rate is confused, and it is not easy to calculate how much degree the observed trends are dominated by the sea-ice physical changes or by the imperfections of test technique. Until now, the agreement with this question has been hardly reached between different researchers. Some researchers insisted that the stress rate has very little effect on flexural strength (Frederking and Timco 1983; Timco and Weeks 2010). The others argued that the flexural strength of sea ice slightly increases with increasing of the stress rate (Ji et al. 2011). One of the main reasons for this inconsistency is inaccuracy of the stress rate. The samples completely crack very soon from the beginning to the end of the loading, approximately within one second (Timco and Weeks 2010). If the sampling frequency is not high enough, the average stress rate is computed less accuracy than that in compression test, where the rate-dependence of compression is clearly observed. However, the flexural strength shows a decreasing trend with the stress rate a little more clearly, when the salinity and temperature of sea ice maximally keep uniform.

Flexural Strength of

Sea Ice, Fig. 2 Flexural strength versus the square root of the brine volume for first-year sea ice (Timco and O'Brien 1994)

Flexural Strength of Sea Ice, Fig. 3 Influence of brine volume on the flexural strength (Ji et al. 2011)

F

This trend enlightens the combination of the brine volume and stress rate to study their coupling effect on the flexural strength of sea ice. Many studies have been focused on the influence of a single factor on the flexural strength of sea ice. In fact, these influential factors are coupled together. Furthermore, the specified factor such as salinity and temperature is hardly controlled to be uniform during the test of sea ice. This causes the inaccuracy of the dependence of the flexural strength on a single factor with the other factors to be constant. Thus, the flexural strength as a multivariate function of temperature, salinity, and stress rate has been proposed. The flexural strength of sea ice can be simulated as a two-parameter exponential equation with the consideration of both brine volume and stress rate (Ji et al. 2011) in Fig. 4. This scheme overcomes the disadvantages of the single factor, but there still need to be more experimental data to determine the fitting equation and its parameters.

$$\sigma_f = ae^{(c+d\dot{\sigma})\sqrt{v_b}}$$

with $a = 2.61$, $c = -5.58$, and $d = 2.09$.

The influence of the scale on the flexural strength is seldom studied, but it is verified by many phenomenon from the large-scale monitor of sea ice such as satellite images (Marsan et al. 2004). For laboratory scale, the sea-ice samples are small volumes, which make the test results hard to be applied into the large-scale condition. Generally, the flexural strength decreases as the

scale become large (Parsonsa et al. 1992; Weiss and Dansereau 2017). For the flexural strength of laboratory, the refined samples could be too small to enclose large quantity of ice crystals. This shortage makes the data not competent to account for grain size effects. Moreover, small samples are likely to reduce the randomness of the distribution of sea-ice flaws. To some degree, the cantilever beam test overcomes this shortage, because it is carried out in situ and maximally preserves the natural flaws of sea ice (Parsonsa et al. 1992). Therefore, we could observe that the flexural strength from the cantilever tests tend to be lower than other measurement methods. However, the conversion equation between different scales has not been given, so much more test data especial from full-scale tests are eagerly to be incorporated to study scale effects.

Loading direction should be another factor influencing the flexural strength. In practice, the direction of the moment is perpendicular to the ice cover, when the interactions between sea-ice covers and engineering structures take place under the current and wave. Thus, the influence of the loading direction on the flexural strength has been paid less attention.

Shortage of Strain Measurement of Sea-Ice Test

As we mentioned, the accurate measurement of strain rate is a key problem to study the

Flexural Strength of Sea Ice, Fig. 4 Curve-fitted flexural strength surface (a), flexural strength contour (b), and stress rate contour (c)

relationship between flexural strength and strain rate. It is not so easy to get the real strain rate, because the length of the time is very short from the beginning of the loading to the break of sea-ice sample. In traditional ice mechanics, displacement actuators, strain gauges, and extensometers are used to measure the deformation of specimen (Timco and Weeks 2010). Those measurements need some operation on the surface of sea-ice sample, and it is likely to bring the local damage and cause the stress concentration. Alternatively, the equivalent displacement is widely adopted to

study the relationship based on the displacement from an indenter (Wang et al. 2019). The loading surface of the specimen and indenter on it move together and thus have the same displacement all the time. Therefore, the strain of the specimens can be deduced from the displacement of indenter without considering the deformation of the rig itself. This method provides only one value to represent the overall deformation of the specimen, even under the assumption that the loading system has enough stiffness compared with that of sea-ice specimen. For sea-ice material, the local variation

in deformation cannot be ignored because of the existence of brine pockets and air bubbles inside of sea ice.

Digital image correlation (DIC) method provides a new concept to obtain strain (rate) from the sequential images. This method has been applied to the deformation measurements of other materials. Based on the DIC, full-field displacement and strain can be accurately obtained by comparing the digital images of specimen surfaces for the initial and deformed states in Fig. 5. Wang et al. (2019) used the DIC to investigate the uniaxial compressive strength and fracture mode for sea ice and lake ice. Moreover, based on the DIC technique, the full-field deformation is accurately deduced, and the damage process of the specimen is clearly obtained at high spatiotemporal resolution.

With the assistance of high-speed camera, the strain can be computed on enough frequency even within a very short time from the loading to the break of sea-ice sample. The DIC technique will facilitate the measurement of sea-ice strain (rate). Then the study of relationship between flexural strength and strain rate will become more accurate. Meanwhile, digital images can be used to capture the local conditions of sea-ice specimens and depict the failure characteristics during the loading process (Ji et al. 2020). This will extend the ability to further explore the complex mechanical behaviors of sea ice.

Discrete Element Method for Simulation of Flexural Strength

Sea ice is composed of solid ice, brine, and gas. This multiphase makes its mechanical properties behave much heterogeneously. Therefore, sea ice is isotropic with granular structures as well as anisotropic with columnar structures. In turn, these differences are reflected to the mechanical properties of the ice (Timco and Weeks 2010). The flexural strength of sea ice is such a mechanical property and depends on many influencing factors such as temperature, salinity, porosity, and grain structure. Consequently, the mechanical properties of sea ice are complex. Experimental investigations in situ or in laboratory do not satisfy the requirement of relationship between flexural strength and its many influencing factors.

Numerical method leverage us another tool to investigate the mechanical properties of sea ice. Considering the multiphase and anisotropic mechanical properties of sea ice, discrete element method (DEM) is being developed to accomplish the goal and has got a better performance. DEM is based on the discontinuous mechanics model, which approaches the real physical composition of sea ice more closely than the traditional numerical methods such as finite element method and finite different method. Several works have been done to look into the failure process of the three-point beam test and to simulate the mechanical

Flexural Strength of Sea Ice, Fig. 5 Digital image correlation applied into the three-point beam test to get the deformation field

behavior of sea ice in response to ocean waves (Xu et al. 2012).

The principal of the DEM was first proposed in the late of 1970s. Since then, it has been developed to simulate the failure process of brittle material such as sea ice (Long et al. 2018; Bateman et al. 2019). For the DEM, sea ice is approximated as an assemblage of the bonded particles, of which each is dominated by Newton’s second law to simulate the mechanical behavior. On microscale, the main parameters of the particle model include normal and shear stiffness, normal and shear bonding strength, particle diameter, sample size, and interparticle friction coefficient, as shown in Fig. 6. When the interparticle stress surpasses a critical threshold, the bonds between particles break. The flexural strength of sea ice can be obtained depending on these micro-parameters in the DEM.

During the simulation using DEM, the particle size, bonding strength, and friction coefficient are the major parameters to influence the flexural strength of sea ice. In order to simulate complex mechanical behavior during the experiment of flexural strength, it is essential to develop an effective method to bridge the gap between the micro-parameters and the macro-strength in the

DEM. In general, these parameters are calibrated and validated according to that of sea-ice strength, as measured in a series of flexural and compressive tests. The assemblage of particles is subjected to the load and then the adjustment of bending stress accomplishes the block fractures in Fig. 7. The interparticle bond strength limits are adjusted until the critical failure stress determined for the numerical sample falls within the ranges confirming to the data from the test of flexural strength.

After filling the gap, the relationship between the flexural strength and physical properties (salinity and temperature) can be checked out. With the development of parallel computation of GPU, the number of the particles can easily reach the million level. As a result, the influencing of

Flexural Strength of Sea Ice, Fig. 6 Parallel bond model between two spherical particles

Flexural Strength of Sea Ice, Fig. 7 Failure processes of three-point bending test (Long et al. 2018)

strain rate on the strength is able to be figured thoroughly, which is not so easy to be obtained for tests in situ or in laboratory. However, there need to be more developments to improve the theoretical basis of DEM numerical approach. Furthermore, the mechanism of more micro-parameter effects on macro-behaviors of mechanics should be analyzed in detail in future works.

FLNG

Ke Zhou
Shanghai Jiao Tong University,
Shanghai, China

Synonyms

FLNG (floating liquefied natural gas); LNG (liquid natural gas); LNGC (LNG carrier)

Definition

Floating liquefied natural gas (FLNG) refers to water-based *liquefied natural gas (LNG)* operations employing technologies designed to enable the development of offshore natural gas resources. Floating above an offshore natural gas field, the *FLNG* facility produces, liquefies, stores, and transfers liquefied natural gas at sea before *LNG* carriers ship it directly to markets (https://en.wikipedia.org/wiki/Floating_liquefied_natural_gas).

Introduction

Due to the growing demand for clean energy, natural gas reserves stranded offshore, which were once considered to be quite challenging, are becoming more and more attractive. Those stranded gas fields are commonly located in deep water and are isolated from onshore infrastructures or offshore pipelines, which challenges their exploitation (Zhao et al. 2014). To overcome

those difficulties, floating liquefied natural gas (FLNG), a concept of offshore unit, has been proposed. One of the most famous FLNG projects, Prelude FLNG, located at western coastline of Australia was put into use in 2018. It is illustrated in Fig. 1.

Floating liquefied natural gas (FLNG) refers to water-based liquefied natural gas (LNG) operations employing technologies designed to enable the development of offshore natural gas resources. Floating above an offshore natural gas field, the FLNG facility produces, liquefies, stores, and transfers liquefied natural gas at sea before LNG carriers ship it directly to markets.

The free floating FLNG can be moored directly above the natural gas field. It will route gas from the field to the facility via risers. When the gas reaches the facility, it will be processed to produce natural gas, LPG, and natural gas condensate. The processed feed gas will be treated to remove impurities, and liquefied through freezing, before being stored in the tanks. LNG carriers will offload the LNG, as well as the other liquid by-products, for delivery to markets worldwide (Fig. 2).

FLNG has its unique hydrodynamic characteristics. Due to the large oil and gas processing topside module, wind loads have considerable influence in motion responses of FLNG. FLNG with single-point mooring system is dominated by the weathervane effect to minimize the

environmental loads, including wind, wave, and current loads, on the vessels. Besides, the coupling effect between ship motions and inner-tank sloshing is strong due to the fluidity of LNG (Fig. 3). Tremendous impact forces of inner-tank sloshing threaten the safety of LNG storage systems and greatly change the hydrodynamic performance of FLNG.

A number of major gas and oil companies are still researching and considering FLNG developments, with several initiatives planned for the future. However, the world's first development of FLNG is Shell's Au\$12bn *Prelude FLNG* project, 200 km offshore Western Australia. Royal Dutch Shell announced their investment in FLNG on 20 May 2011, and construction began in October 2012. Numerous other FLNG projects are also underway in regions like North America, West Africa, Brazil, and Southeast Asia. The following shows the distribution of some ongoing FLNG projects worldwide (Fig. 4) (Lovatt 2017).

Development History

Studies into offshore LNG production have been conducted since the early 1970s, but it was not until the mid-1990s that significant research backed by experimental and numerical development began.

The concept design of FLNG was firstly initiated by Shell in 1969. Then, in 1978, FLNG was firstly proposed as an engineering project in

FLNG, Fig. 1 Snapshot of prelude FLNG

F

FLNG, Fig. 2 Offloading process between the FLNG and an LNG carrier

FLNG, Fig. 3 Couplings between inner-tank sloshing and ship motions

exploitation of gas and oil fields of Kangan, Iran. The first generation of FLNG, Kangan FLNG, was converted from two tankers that are combined side by side to enlarge the deck area (Howard and Andersen 1979) (Fig. 5).

In 1997, Mobil developed a FLNG production concept based on a large, square structure (160 m $\times$ 160 m) with a moonpool in the center. The Mobil proposal was sized to produce 6 million tons LNG per year, with storage provided on the

structure for 250,000 m³ of LNG and 103,000 m³ of condensate.

In 1999, a major study was commissioned as a joint project by Chevron Corporation and several other oil and gas companies. This was closely followed by the so-called “Azure” research project, conducted by the EU and several oil and gas companies. Both projects made great progress in steel concrete hull design, topside development, and LNG transfer systems.

FLNG, Fig. 4 Distribution of FLNG projects worldwide

FLNG, Fig. 5 Kangan FLNG

Since the mid-1990s, Royal Dutch Shell has been working on its own FLNG technology. This includes engineering and the optimization of its concept related to specific potential project developments in Namibia, Timor-Leste/Australia, and Nigeria. In July 2009, Royal Dutch Shell signed an agreement with Technip and Samsung allowing for the design, construction, and installation of multiple Shell FLNG facilities.

As of November 2010, Chevron Corporation was considering an FLNG facility to develop offshore discoveries in the Exmouth Plateau of Western Australia, while in 2011, ExxonMobil was also waiting for an appropriate project to launch its FLNG development.

As a result, it is found that the progresses of FLNG development were mainly contributed by large global energy companies due to the complexity of the FLNG systems and the great amount of investment. Meanwhile, a number of shipyards, classification societies, and equipment suppliers have fierce competition and formed a number of research and development alliance to carry out engineering project.

Main Structure of FLNG

FLNG is equivalent to placing an offshore gas liquefaction plant on the deck of a ship hull. However, the deck area is only 1/4 of that of the onshore natural gas liquefaction plant, so that the liquefaction system process should be very compact (Fig. 6).

The process mainly includes preparation of refrigerant nitrogen expander cycle system, liquefaction and condensation extraction system, and gas processing system. The whole system should

FLNG, Fig. 6 Layout of FLNG structures

F

be compact, safe, and have low sensitivity to hull movement. Therefore, the main structure of FLNG includes LNG processing equipment, LNG storage system, single-point mooring system, LNG offloading system, and living building, helicopter platform, and flare tower. Figure 6 shows the layout of the main structures of FLNG.

Main Characteristics of FLNG

Advantages

With the maturity of FLNG technology, this engineering concept has been accepted by many energy companies with considerable advantages.

Economic – Utilizing FLNG to develop offshore gas fields has put an end to a single transportation mode where offshore gas fields can only be transported ashore by pipelines, saving large transportation costs and occupying no land space. Besides, FLNG can also be reused twice after the end of gas field mining and be installed in other natural gas fields with higher economic performance.

Environmental – The device can be installed far away from populated areas and is safe and environmentally friendly. Avoiding construction also helps preserve marine and coastal environments. Additionally, environmental

disturbance would be minimized during the later decommissioning of the facility, because it could be disconnected easily and removed before being refurbished and redeployed elsewhere.

The above advantages of FLNG make it the preferred equipment for developing small and mid-sized marginal gas fields offshore.

Technical Challenges

Moving LNG production to an offshore platform presents a set of challenges. In terms of the design and construction of the FLNG facility, every element of a conventional LNG facility needs to fit into an area roughly one quarter the size while maintaining appropriate levels of safety and giving increased flexibility to LNG production. Main challenges include the liquefaction of natural gas, LNG storage, and LNG offloading between FLNG and carriers.

At present, the natural gas liquefaction technology onshore is relatively mature, but offshore operations make the design standard of liquefaction process much different. Liquefaction process of FLNG systems more emphasizes safety, simplicity, compactness, and adaptability to different gas fields and ocean environment. Three methods of liquefaction are normally used in FLNG, including cascade cycle, mixed refrigerant

cycle (MRC), and expander cycle, while they barely satisfy the harsh operation conditions in open seas.

For the storage of LNG, the LNG containment systems need to be capable of withstanding the damage that can occur when the sea’s wave and current motions cause sloshing in the partly filled tanks. Also, LNG should be kept in the low temperature of minus 162 °C during storage process, and the wall of inner tanks will bear a certain vapor pressure. In order to avoid the dangerous situation, the material of the storage tanks and its insulation are very important. LNG tanks that have been successfully put to use can generally be divided as MOSS type, SPB type, and GTT type (Fig. 7).

Side-by-Side Offloading Operation

FLNG (floating liquefied natural gas) system has great safety, economic, and environmental

advantages in the development of marginal gas fields by means of liquefying the natural gas on the production barge and offloading it to a LNG carrier (LNGC). Instead of a conventional method of gas transportation through long pipelines, the cryogenic nature of liquefied natural gas (LNG) determines a small offloading distance between FLNG and LNGC with a side-by-side configuration in offloading operation (see Fig. 8). LNG loading arms (see Fig. 9), as a substitute for hoses, also require the side-by-side offloading configuration, while the relative motions during side-by-side offloading will induce large angles in the offloading arms.

With the increasing transportation amount of LNG, side-by-side offloading operation is a proven methodology for ship lightering and is successfully implemented in the first FLNG project, Prelude FLNG. Many approaches have been developed to investigate and ensure the safety and reliability of offloading operations.

FLNG, Fig. 7 LNG tanks of different types

FLNG, Fig. 8 Narrow gap between side-by-side FLNG and LNG carrier

F

FLNG, Fig. 9 LNG loading arms on the FLNG broadside

Nevertheless, there are still challenges that hinder the side-by-side offloading operations. Due to the small gap width (about 4–6 m) between side-by-side moored FLNG and LNG carrier, hydrodynamic interactions are stronger and complex. Relative motions should be strictly controlled because of high risks of collisions (Soares et al. 2015). As a result, the side-by-side offloading operations can only be implemented in relatively benign waters or weather conditions. Special mechanical connection systems, such as fenders and hawsers, are compulsorily deployed to constrain the relative motions for enhancing operational safety.

Besides, some special hydrodynamic phenomenon can also be observed in the gap region that might cause damage to the offloading equipment. For instance, strong wave resonances can be induced at certain wave frequencies in the confined zone between side-by-side vessels. The amplified waves have negative influence on the hydrodynamic performances of both vessels in close proximity and potentially threaten the safety of transport pipelines above the waves. Extensive works have been carried out to study the resonant modes and frequencies of the gap wave field (Yeung and Seah 2007; Molin 2001).

Hydrodynamic Performances of Side-by-Side Moored Vessels

The hydrodynamics of two side-by-side vessels is more complex than that for a single vessel. The difficulty lays in the hydrodynamic interactions, the shielding effects, and the wave resonance observed in the gap between the two vessels.

Shielding Effect

When two vessels locate in close proximity, the shielding effect of parallel vessels in oblique waves is quite obvious. Figure 10 shows the layout of two side-by-side vessels under different wave directions. For the vessel at lee side, as the LNGC in 135deg waves, the wave loads and motion responses are found to be suppressed due to the shielding of vessel at weather side.

Shielding effect of each vessel is different due to its size, displacement, and wave directions. Comparisons of motion responses under different wave directions show that motion responses of FLNG are insusceptible to the change of wave directions because of its large inertia, while motion responses of LNGC at the lee side (135deg) are more stifled due to the stronger shielding effect of FLNG. Interestingly, either LNGC at lee or weather side has smaller amplitude of sway or yaw motion than that free floating solely, owing to the suppression effect of the FLNG aside.

Gap Wave Resonance

Gap wave resonances are induced by incoming waves with frequency close to the natural frequencies of the gap water. Wave energy is gradually accumulated in the gap zone, and resonances finally get developed. Hence, gap wave elevations can be amplified even in mild weather conditions.

Divided by the types of restoring forces, two resonant modes can be defined, namely, the piston mode and sloshing modes (see Fig. 11).

For the piston mode, gap water (gray area between two hulls in Fig. 11a) acts like a piston moving up and down periodically dominated by the gravity. For the sloshing modes at higher frequencies, a complex pattern of wave amplification and cancelation can be seen in the gap region. Standing waves are triggered by the interference between waves reflected back and forth at the gap exits into the open ocean (Fig. 11b). The gray area shows the parallel part of the gap. The blue line is the incoming wave, the dotted line the reflected wave.

Many numerical studies have been implemented to unravel the physics of resonant gap waves. In addition to computational fluid

mechanics (CFD) methods, diffraction computation based on potential flow theory is also widely used. Nevertheless, resonance behavior of the wave in the gap always tends to be overestimated using standard diffraction programs. Viscous effects, neglected in diffraction theory, may be more dominantly present at the bilges of the keel due to resonant flow between the bodies.

Mechanical Connections

During offloading operations, mechanical connections between FLNG and LNGC, like hawsers and fenders (as shown in Fig. 12), are used to restrict fierce relative motions between vessels and lower the intensity of collisions. The LNGC are moored to the FLNG in side-by-side configuration with hawsers having the segments of nylon stretchers and steel wires (yellow lines in Fig. 12a). To avoid hard collisions of two adjacent vessels, fenders are also used to soften the contacts between two huge floaters (Voogt and Brugts 2010).

Normally, the fenders are floating on the free surfaces in the gap zone, and the hawsers are located obliquely at the bow, stern, and middle

FLNG, Fig. 10 Illustration of shielding effect in oblique waves

FLNG, Fig. 11 Different resonant modes of gap waves

FLNG, Fig. 12 Illustration of hawsers and fenders

FLNG, Fig. 13 Layout of hawsers and fenders

areas (see Fig. 13). Hawsers are pretensioned to restrain the relative motions in the horizontal plane, mainly the surge and yaw motions. The time series of the forces acting on the fenders are in the form of pulses, which indicates that the two vessels are separated in some cases and there are also many collisions between the two vessels (Zhao et al. 2014).

Both the pretensions and the stiffness of the hawsers can significantly affect the hydrodynamic performance of an FLNG system in side-by-side offloading operation, such as the trajectories of the vessels, the relative motion responses between the two vessels, and the loads acting on the hawsers and the fenders. The decrease of the pretension and the stiffness of the hawsers will lead to a reduction of collisions between the two vessels, but an increase of the relative motions between the two vessels in horizontal plane.

Technical Challenges

Offloading Arm

For transportation of liquid natural gas from FLNG to LNGC, novel offloading arms have been developed to overcome the relative motions between two vessels. The company FMC Technologies in France is famous for the offloading arm design capability and has been taken the job for Prelude FLNG of Shell offloading arm design (see Fig. 14). The arm can swivel, rotate, and follow the motion of LNGC for over 15 h during offloading operation. Besides, the arm should perform in extreme cold for the LNG should be stored in -162°C . Once the movement of arm exceeds the safe limit in extreme sea conditions, it should automatically break away from the LNGC and release the LNG left between two valves in the connection head (like the white gas in Fig. 14).

FLNG, Fig. 14 LNG offloading arms

FLNG, Fig. 15 Deployment of offloading arms on FLNG

In FLNG offloading operation, a group with six to eight offloading arms can be deployed on the starboard of the vessel to guide the pipelines to LNGC (Fig. 15). In such circumstance, LNG can be transferred efficiently and safely in side-by-side configuration.

Offloading Pipe

Offloading pipe should withstand extreme low temperature and the fatigue risks due to relative motions between two vessels. Hence, the pipe should have outstanding heat-insulating property using low-temperature-resistant materials. Vacuum annular is adopted to cut off heat transfer between LNG and the air outside. Details of the pipe structure can be obtained

FLNG (Floating Liquefied Natural Gas)

► FLNG

Floating Bridge

Yuwang Xu
School of Naval Architecture, Ocean and Civil Engineering, Shanghai Jiao Tong University, Shanghai, China
State Key Laboratory of Ocean Engineering, Shanghai Jiao Tong University, Shanghai, China

Synonyms

Floating curved bridge; Floating suspension bridge; Pontoon bridge; Ribbon bridge

Definition

A floating bridge is a continuous bridge supported by the buoyancy of a required number of pontoons or floating rafts instead of fixed piles and is a means for pedestrians and vehicles to cross rivers or streams. It is mainly suitable for two scenarios. One is a temporary bridge that can be used in emergency rescue or warfare for relief supplies, wartime troops, weapons, and equipment to quickly pass river barriers. The other one is a permanent civil bridge to cross rivers or seas where the width and the water depth are so large or the bottom is covered by soft silt so thick that it is technologically easier and more economical to utilize floating foundations.

Scientific Fundamentals

Historical Development

The term “floating bridge” refers to a bridge floating on the water supported by a required number of boats or pontoons instead of bridge piers. Before the twentieth century, floating bridges were mostly used for military warfare, so they were mostly used temporarily. The earliest historical record of floating bridges is in China. It is recorded in the *Shi Jing* (Book of Odes) that King Wen of Zhou was the first to create a pontoon bridge in the eleventh century BC. The first permanent floating bridge was constructed in the Qin Dynasty (221–207 BC). Then, during the Eastern Han Dynasty (25–220 AD) and Song Dynasty (960–1279 AD), various pontoon bridges spanning the Yellow River and Yangtze River were constructed (<https://en.wikipedia.org/>). Among them, the Guangji Bridge was constructed in 1171 and renovated in 2007, as shown in Fig. 1. It is a combination of fixed and floating bridges with a total length of 518 m. The floating part is 97.3 m long and is supported by 18 wooden boats.

In Europe, the first floating bridge was built by the Persian Emperor Darius to cross the Bosphorus as he invaded Greece approximately in 500 BC, as recorded by the Greek writer Herodotus. Then, in 480 BC, Xerxes I built a pontoon bridge crossing the Hellespont to transport a large army to Europe (<https://en.wikipedia.org/>), as illustrated in Fig. 2.

Floating Bridge, Fig. 1 Guangji Bridge in China. (Photograph by Luis Evers; from Wikimedia)

Floating Bridge, Fig. 2 Construction of Xerxes' bridge of boats. (Photograph by A. C. Weatherstone)

In the Middle Ages and early modern period, pontoon bridges were widely used in wars. During the Fifth Crusade, the Crusaders built two pontoon bridges across the Nile. One of them was supported by 38 ships. This kind of bridge was also used in the Battle of Rio Bueno by the Spanish army in 1654, the Battle of Montebello by French troops in 1800, and the American Civil War.

During the twentieth century, floating bridges were still used for cross-river operations in the war, such as the First and Second World Wars, as shown in Figs. 3 and 4. Meanwhile, with the development of bridge construction technology and the special terrain requirements of crossing rivers and seas, more permanent civil floating bridges have appeared, especially in the United States and Norway, and have received widespread attention.

Classification

Pontoon Road Bridge

From ancient days to the present, the design of the pontoon road bridge has not undergone major changes either for war or civil use. The roadways and the supported floating pontoons are normally separated. In war, for temporary use, the pontoons are usually designed as smaller ships or rafts. Meanwhile, for the modern permanent civil floating bridges, the pontoons are mostly made of reinforced concrete or steel structures.

Ten of the longest pontoon bridges for civil use are listed in Table 1 (Kvåle 2017). These have been constructed because either the bottom topography or the length and depth are not appropriate for bridges supported by fixed foundations. The pontoon bridges in the USA and Japan listed in Table 1 are all due to the bottom topography. For instance, at the location of the Evergreen Point Floating Bridge, the lake has a water depth of 61 m atop 61 m of soft silt. Constructing fixed foundations would be technically more

Floating Bridge, Table 1 Ten of the longest pontoon bridges for civil use (<https://www.enr.com/>)

F

challenging as well as too expensive. In contrast, in Norway, floating bridges are built mainly for the crossing of fjords with a large width and water depth. Among them, the Salhusfjorden spanned by the Nordhordland Bridge has a water depth of 320 m and width of 1246 m. Norway is currently in the process of designing a new pontoon bridge for the Bjørnafjorden, which has a span and a depth of more than 5,000 m and 550 m, respectively. In addition, the design of arch-shaped bridge girders and pontoons without side anchors is more popular in Norway, as shown in Fig. 5.

From the perspective of the shape of the pontoon, the floating bridges in the USA listed in Table 1 are mainly supported by continuous pontoons. The bridges in Norway, Guyana, and Japan in the table are all designed using discrete pontoons. This is partly attributed to the environmental conditions in the different locations. In Norway, the bridges are normally located in open seas where the wind, waves, and current are very strong. The use of discrete pontoons with the long sides of the buoy parallel to the main wave and current directions can effectively reduce the environmental load and ensure safety. In the USA, the Evergreen Point Floating Bridge

and Lacey V. Murrow Memorial Bridge are in the inner lake and suffer relatively more gentle environmental conditions. The continuous design yields better dynamic performance.

Military Ribbon Bridge

In a military ribbon bridge, the foot boat and the roadway are normally merged into a whole. It is different from the pontoon road bridge in which the roadway and the floating pontoons or small supported ships are constructed separately. The advantage is that it can greatly reduce the number of components to ensure more rapid erection and disassembly with fewer operators. Due to its outstanding features in rapidity and mobility, the ribbon bridge is widely used in emergency rescue or warfare for relief supplies, wartime troops, weapons, and equipment to quickly pass river barriers.

The military ribbon bridge was developed earlier in Europe and America. The first ribbon bridge was designed by the Soviet Union after World War II and named the PMP ribbon bridge, as shown in Fig. 6. It was deployed in 1962 and subsequently adopted by Warsaw Pact countries and other states employing Soviet military

equipment. In 1969, the US military began to develop a similar type of the PMP ribbon bridge, which was officially equipped with troops in 1976. In 1974, Chinese troops designed and manufactured the first-generation “74-type” ribbon bridge. Since the 1980s, countries have begun to compete with ribbon bridge equipment upgrades, such as the US Improved Ribbon Bridge (IRB), the German M3 self-propelled ribbon bridge, and the French EFA frontline crossing equipment, as shown in Fig. 7.

Floating Suspension Bridge

The concept of floating suspension bridges is a combination of offshore ocean engineering and bridge engineering proposed by the Norwegian Public Road Administration. It mainly consists of two components, i.e., a traditional suspension bridge above the water and several tension leg platforms (TLP) in the water. The design of three-span suspension bridges for the crossing of Bjørnafjorden along the E39 highway of Norway is shown in Fig. 8. The fjord has a length of over

Floating Bridge, Fig. 6 Hungarian PMP Pontoon Bridge that crosses the Sava river at Slavonski Brod, Croatia, 1996. (Photograph by SSGT Edward W. Nino - <http://www.defenseimagery.mil>)

Floating Bridge, Fig. 7 US and German Army units that cross the river Elbe using German M3 amphibious bridging vehicles, 2015. (Photograph by Sgt. Jesiah Dixon, U.S. Army)

5 km and a depth of approximately 550 m. For such great water depths, bridges with foundations fixed on the seabed are not advantageous. The performance or the feasibility of the floating suspension bridge has been evaluated by several consultancies in Norway since 2014, and the work is still continuing.

In these new concepts, the main cables are supported by two fixed pylons at each end and one or two floating pylons in the middle of the bridge. The bottom part of the floating pylon is similar to tension leg platforms moored by four groups of tethers, providing a high stiffness in heave, pitch, and roll. The TLP, originally developed for the oil and gas industry, is the main point that enables the bridge to be built on greater depths than what had been possible for the fixed type (Veie and Holtberget 2015). In the design of the bridge across the Bjørnafjorden, each of the main girder spans has a length of 1385 m. The pylons are 198 m high and have a draft of 65 m. The water depth is 550 m and 450 m at the left and right floating pylons, respectively.

Key Technology

Environmental Loads

For a bridge with a fixed foundation, wind, traffic, and earthquakes are usually considered. In addition to such traditional actions, wave-, current- and tide-induced load effects must also be included in the pontoon bridges, which bring more challenges into the design.

Floating Bridge, Fig. 8 Three-span suspension bridge with two floating pylons. (Illustrated by Arne Jørgen Myhre, Statens Vegvesen)

The wind action on the slender structures, such as the steel column, tower, and cable, is usually modeled by viscous drag forces. For bridge girders, it can be more complicated. In principle, it is composed of the mean and buffeting forces due to the mean and turbulent wind velocities and the self-excited forces induced by the motion of the structure (Xu et al. 2017). The mean and buffeting forces are normally calculated based on quasi-steady theory using the frequency-dependent drag, lift, and torsion moment force coefficients and their derivatives with respect to the angle of attack (Strømmen 2010), which can be achieved from wind tunnel experiments or CFD simulations (Helgedagsrud et al. 2019; Siedziako and Øiseth 2018). The self-excited force is relatively more complicated in the simulation since it is related to the oscillation frequency of the structure. Theodorsen's and Wagner's functions are the renowned expressions representing the aerodynamic motion-induced forces on an airfoil in the frequency and time domains, respectively (Theodorsen 1935; Wagner 1925). The theories are generalized to describe the motion-induced forces acting on a bridge deck by other researchers. The commonly used expression for a bridge deck includes the aerodynamic derivatives, indicial function, rational function, and state-space model (Øiseth et al. 2012; Scanlan and Tomo 1971).

The hydrodynamic actions consist of hydrostatic forces, wave excitation forces, and radiation forces. The hydrostatic forces are frequency independent and can provide a restoring force for the structures, usually modeled as a spring in the static and dynamic analyses. The wave excitation forces related to the fluctuating pressure on the submerged surface of the pontoons are caused by incident waves assuming that the structure is fixed, which consist of first-order, second-order difference and sum-frequency excitation forces (Faltinsen 1993). The magnitude of the first-order forces is always larger than that of the second-order forces and is defined by a transfer function that can be obtained by potential theory. The natural frequencies of the low-order modes of the long and slender floating bridge are well below the energy content in the wave spectra such that

these modes will not be excited by first-order excitation forces. However, the difference-frequency forces can cause wave excitations in this frequency range even though they are of small amplitude. The sum-frequency forces introduce excitation at higher frequencies compared to the first-order excitation forces, which are unlikely to be an important factor for the floating bridges. When a floating structure oscillates in waves or still water, it generates outgoing waves, resulting in oscillating fluid pressures on the surface of the body. The integrated hydrodynamic pressures give rise to radiation forces, which are a combination of frequency-dependent added mass and potential damping.

The current-induced loads on the pontoons are also normally modeled by viscous drag forces using the modified Morison equation (Morison et al. 1950). The effect of the tide is also quite important for floating bridges, which is modeled as a constant force equal to the product of the tide level and the hydrostatic restoring stiffness.

Hydro- and Aeroelastic Response Analysis

Different from the oil platforms that are normally considered as rigid bodies, floating bridges are super slender structures, and elastic deformation is of the same magnitude or even much larger than rigid-body motion. The coupling between the elastic deformation and the wave-induced or aerodynamic loads increases the complexity of understanding the dynamic characteristics of such structures.

For ribbon bridges, only hydroelastic response should be considered. Research on this topic has been ongoing since the 1970s. Two-dimensional hydroelastic theory, originating from strip theory, was widely used and studied at that time. In 1984, Wu first proposed a three-dimensional hydroelastic theory in the frequency domain (Wu 1984). It can be applied to very large floating structures with any complex geometry. Subsequently, a great amount of research on time-domain hydroelastic theory was performed in order to take into consideration moving loads or different kinds of nonlinear features (Chen et al. 2003; Wei et al. 2018).

Floating Bridge, Fig. 9 Structural deformations of ship-girder collision (Sha et al. 2019)

For bridges supported by discrete floating pontoons, such as the Nordhordland Bridge (in operation) and the floating suspension bridge (still in design), they can be considered a multi-body system (floating pontoons) connected by a simplified beam (bridge girder) in the hydro- and aeroelastic response analysis. For the aeroelastic theory, it is basically the same as for traditional fixed-type bridges. The main difference is that the multibody hydrodynamics and the aeroelastic response have to be considered simultaneously (Xu et al. 2018a, b).

For the bridge supported by continuous pontoons, such as the Lacey V. Murrow Memorial Bridge, both hydro- and aeroelastic responses should carefully be taken into consideration.

Ship Collisions

Ship collision is a great threat to bridges across navigation waterways. Possibilities exist for collisions between various types of surface ships with different sizes and speeds and bridge girders and pontoons. Such a collision is a complex nonlinear dynamic process occurring in a very short time but with large impact loads. A variety of nonlinear properties of materials, geometry, and contact introduce tremendous challenges into the accurate numerical simulation of the collision process. To reduce collision occurrence, various measures such as specifying ship lanes (vertical and horizontal as well as keel clearance at the bridge), speed limits, safety zones, traffic control,

and surveillance should be put into effect (Moan and Eidem 2020).

Compared to bridges with fixed foundations, the floating pontoon bridges are more flexible and are likely to experience a large deformation under ship collision loads. Therefore, if the collision energy was assumed to be absorbed locally, as is normally done on fixed type bridges, the local deformation would be significantly overestimated for floating bridges since the global motion can also contribute to the energy dissipation (Sha et al. 2019). Local and global responses of a new concept of floating bridge in Norway under collisions between ships and bridge girders have been investigated. A traditional local collision load estimation approach was first employed to achieve the relation between the force and local deformation, as shown in Fig. 9. Then, in the global collision analysis, the ship is modeled by a mass-spring system connected to the bridge, as shown in Fig. 10. The stiffness of the spring is determined by the force-deformation curve achieved in local analysis. It is found that approximately 40% of the collision energy can be dissipated by the global motion of the bridge.

Key Application

Lacey V. Murrow Memorial Bridge

The Lacey V. Murrow Memorial Bridge is the first bridge to cross Lake Washington in Seattle, USA.

Floating Bridge, Fig. 10 Global collision analysis (Sha et al. 2019)

It was opened in 1940. Since the bottom of Lake Washington is covered by very thick mud deposits, it was challenging to build fixed foundations. As an alternative and feasible design, the bridge deck is supported by 22 floating pontoons made of reinforced concrete with dimensions of $106.7 \times 18 \times 4.3$ m. Each one is divided into 96 cells with four across the width and 24 along the length (Dusenberry et al. 1995). It is the world's first floating bridge to be built using concrete pontoons. Adjacent pontoons are bolted together end-to-end and kept in position by side anchors. At the ends, the roadway is elevated on beams and columns and is sloped upward to the transition spans connected to the fixed spans. Fixed spans connected the floating bridge to the approach highways.

The bridge was closed for refurbishment on June 23, 1989. The Washington State Department of Transportation decided to use hydrodemolition to remove the unwanted materials on the bridge and pontoons. The water from hydrodemolition was considered contaminated and was not allowed to flow into the lake. By calculation, it was found that the floating pontoons had the potential to store the contaminated water temporarily. During the Thanksgiving Day holiday (November 22–24, 1990), the bridge was attended intermittently by only a few people. Simultaneously, a strong storm passed by the lake. On the last day of the holiday, it was found that one pontoon was

Floating Bridge, Fig. 11 The Lacey V. Murrow Floating Bridge sank to the bottom of Lake Washington on Nov. 25, 1990 (<https://mynorthwest.com/>)

beginning to sink, as shown in Fig. 11. Although a significant effort of pumping the water out of the pontoon had been done, it was too late to stop the disaster (Dusenberry et al. 1995). In the end, an 850-m-long section of the bridge sank to the bottom of the lake. The disaster postponed the reopening of the bridge for 14 months and resulted in a large financial loss.

Bergsøysund Bridge in Norway

The Bergsøysund Bridge is a floating pontoon bridge on the western coast of Norway with a length of 930 m, operated by the Norwegian Public Road Administration, as shown in Fig. 12. It spans the Bergsøysund fjord with a water depth of 320 m, providing a permanent road link between the islands of Aspøya and Bergsøya. It consists of

F

Floating Bridge, Fig. 12 The Bergsøysund Bridge. (Photograph by NTNU/K. A. Kvåle)

a continuous steel truss superstructure and seven floating pontoons. The pontoons are shell structures that are made of lightweight aggregate concrete, providing buoyance force or restoring stiffness in the vertical and torsional directions. The bridge has no side-mooring or anchoring and relies fully on a flexible rod connected to an abutment on the land at each end, resulting in a construction method that does not involve excavation of the seabed (<http://www.eng.mortemor.com/>). To ensure sufficient lateral stiffness, the bridge is designed in an arc shape with a radius of curvature of 1300 m.

The Bergsøysund Bridge has been instrumented with an extensive monitoring system since it was opened in 1992. Six wave height sensors and five anemometers are installed to collect wave and wind data at the site in real time (Kvåle and Øiseth 2017). The dynamic response of each pontoon is monitored online through tri-axial accelerometers and the Global Navigation Satellite System. Due to the success of the Bergsøysund Bridge, another similar but longer floating pontoon bridge, the Nordhordland Bridge, was opened in 1994.

Improved Ribbon Bridge (IRB)

The Improved Ribbon Bridge (IRB) is a modular and transportable bridge system developed by General Dynamics European Land Systems. It is designed as an efficient way for heavy military

Floating Bridge, Fig. 13 Improved Ribbon Bridge (<https://militaryleak.com/>)

equipment such as loaded heavy equipment transporters, weapons systems, wheeled/tracked combat vehicles, trucks, suppliers, and troops to cross wet-gap obstacles, such as rivers or streams.

A complete ribbon bridge is normally composed of two ramp bays at the end connected to the land and a number of interior bays between them, as shown in Fig. 13. The number depends on the width of the specific wet-gap obstacle. The bays can be disassembled and transported on aircraft, helicopters, trucks, and railway cars in a folded condition.

The IRB ramp and interior bay is a four-pontoon module with two inner pontoons that form a wide roadway and two outer pontoons that provide walkways on both sides, as shown in Fig. 14. The outer pontoons are designed in a

Floating Bridge, Fig. 14 The IRB ramp and interior bay (Trim and Bennett 2020)

bow shape in order to decrease the current-induced drag loads acting on the bridges in the perpendicular direction. The four pontoons are joined by hinges and pins along their adjacent edges that allow the bay to fold and unfold. It unfolds automatically by the force of gravity and buoyancy generated as the bay is released and begins to float (Trim and Bennett 2020). Since they have no power system, the modules have to be allied and connected manually.

Fluid Effects During Iceberg-Structure Interactions

Introduction

The ice impact forces on a fixed or floating offshore structure are an important structural design consideration in the Arctic region. To predict the impact forces, a knowledge of velocity, acceleration, and location of both ice mass and structure before impact is necessary. These are heavily influenced by the ice conditions, the structure geometry, the hydrodynamic forces, as well as the location of the ice mass relative to the structure.

The hydrodynamic effects of the surrounding water play an important role in the analysis of collisions between ice mass and fixed or movable structure. For instance, hydrodynamic forces cause an ice mass or floating structure to move

before the actual collision and consequently affect the impact bodies' velocities and trajectories. Especially, for small ice masses and bergy bits, these effects are more obvious (Sayeed et al. 2017). This will result in inaccurate predications of absorbed energy and impact forces. Therefore, it is necessary to take into account the hydrodynamic effects when dealing with ice-structure interactions.

The hydrodynamic effects such as negative wave drift force, fluid cushioning, shadowing, reduction in impact velocity, and hydrodynamic damping are very complex. A number of studies have investigated fluid effects during ice-structure interaction. According to the locations of the ice mass relative to the structure, the studies in this area can be classified into three phases, namely, far-field, near-field, and contact phases.

Far-Field Phase

The far-field phase focuses on ice mass drift in open water, where the location of the ice mass is far from the structure and their interaction can be neglected. The motion of the ice mass is heavily dependent on the ice properties, the size and shape of the ice, and environmental conditions.

Hsiung and Aboul-Azm (1982) developed a mathematical model to predict iceberg drift pattern. The model included the wave drift force and the other conventional force components such as forces due to wind, current, Coriolis effect, and geostrophic effect. Trajectories of two icebergs with the wave effect and without the wave effect were calculated and compared with field results. It was shown that the wave effect had a significant improvement in the correlation.

Pavec and Coche (2007) proposed a model to predict the short-term drift of an iceberg by a prediction of the forces that act on the object. In the model, the wave effect was included, which improved significantly the estimation in some cases. To deal with the uncertainties associated with the parameterization of waves, a stochastic calculation was also included into the model. The calculated drifts were generally in good agreements with the test data. The results emphasized

the need of precise current forecast and the importance of the wave-induced force.

Near-Field Phase

In the near-field phase, the hydrodynamic effects are complex since the surrounding flow fields are modified for different distances between the ice mass and structure. The presence and the motion of the other body have significant effects on the drift motion of the ice during the approach.

Isaacson (1987) investigated the motions of an ice mass due to waves and a current near an offshore structure, in which the nonlinear interactions between waves and current were neglected. The drift trajectory which takes into account the current drag, the wave drift forces, and the added mass effects was obtained through a time-stepping procedure. However, this three-dimensional model was not applicable to situations where the separation distance between the two objects was very small compared to the size of the bodies due to the limitations on facet size. In order to achieve accurate results for very small separation distances, Isaacson and Cheung (1988a) proposed a two-dimensional model for two cylinders of arbitrary shape on the basis of potential flow theory and the boundary-integral method. The results showed that the added mass coefficients and convective force coefficients varied significantly when the separation distance was less than twice the diameter of the drifting cylinder. This model was unsatisfactory when flow separation has a significant effect on the interactions due to the limitations of the potential flow theory.

Gagnon (2004) investigated the hydrodynamic interaction between floating glacial ice masses and a transiting tanker through physical model experiments. Figure 1 shows the small sphere and tanker during a typical test. In contrast to the case where an iceberg was moving in current toward a larger fixed structure and considerable reductions of impact velocity occur due to hydrodynamic effects (Isaacson and McTaggart 1990a), the experimental data indicated that the magnitude of surge speed and sway speed were very low and would not significantly reduce impact speed in the

A photograph of a typical test using the small spherical ice mass model (Gagnon 2004)

F

Fluid Effects During Iceberg-Structure Interactions, Fig. 2

The setup of the numerical model (Tsarau et al. 2014)

scenarios tested. In addition, the results showed that waves tended to increase the degree of sway values. Due to the degree of complexity of the hydrodynamic interaction, numerical method would be more applicable than analytical modeling.

Tsarau et al. (2014) proposed a numerical model to analyze the hydrodynamic interactions between a floating structure and fragmented sea ice, in which rigid-body dynamics and fluid flow around the structure and ice were included (see

Fig. 2). In order to validate this numerical model, a number of physical model tests were conducted (see Fig. 3). It was found that the model was applicable for estimating the hydrodynamic forces on ice upstream of a structure, but it was unsatisfactory when the potential flow assumptions fail. Besides, the experimental data showed that the hydrodynamic forces on the submerged ice model that occur in response to the approaching floater were rather complicated and change values between positive (ice pushing) and negative

Fluid Effects During Iceberg-Structure Interactions, Fig. 3 The setup of the experimental model (Tsarau et al. 2014)

(suction). It was also found that the magnitudes of the forces had a linear relationship with the square of the transit speed as long as the ice was in front of the structure and the motion was steady.

Lee and Nguyen (2011) studied the bow shoulder and side collision responses between a liquefied natural gas carrier (LNGC) and a cubic iceberg using the fluid-structure interaction (FSI) analysis technique of LS-DYNA code. Several collision scenario types were considered, such as moving forward of LNGC in the cases of no detection or no evasion of iceberg, evasion of iceberg by LNGC, and iceberg in the stationary of current condition. The results showed that the iceberg was affected by the wave-making of the LNGC, especially the relative drift velocity of the iceberg that was induced by the pressure from squeezing water layer entrapped between the iceberg and the LNGC. It was also found the significance of bank effect in the flow between very close floating bodies.

Ahmed et al. (2016) have investigated the most relevant parameters affecting the multi-body hydrodynamic behavior of level ice and a single

floater. It was observed that a near-field ice floe significantly effects on the hydrodynamic RAOs of the floater. The results indicated that the most important parameters were wave direction, ice floe distance, and ice floe orientation, and the most enhanced responses were the sway and pitch.

Contact Phase

The contact phase concerns the impact energy and the impact force which are heavily dependent on the impact velocity and the hydrodynamic coefficients. The hydrodynamic forces acting on the model can be classified as drag, buoyancy, and added mass forces. An important parameter in collision is the added mass of ice and floating structure.

A number of studies have used constant added mass (CAM) terms to take hydrodynamic effects into account in analyses of ice-structure or ship-ship interactions. Minorsky (1959) has proposed a method, which assumes that the hydrodynamic effects are represented by an increased inertia force due to added mass effect. He used a constant value of 0.4 for the sway added mass coefficient of the struck ship. Swamidas et al. (1986) conducted experimental and numerical studies to investigate a semisubmersible and a GBS subjected to iceberg and bergy bit impact. The added mass coefficient of the bergy bit was assumed as 0.5, and this value has been normally used for the impacting ice feature (Cammaert and Tsinker 1981; Johnson and Nevel 1985; Matskevitch 1997; Liu and Amdahl 2010). In the study of Isaacson and McTaggart (1990b), it was concluded that the infinite frequency added mass can be used for collisions of short duration, and zero frequency added mass can instead be used as a conservative estimation of the effective added mass for longer duration collisions.

However, this method with assumption of constant added mass neglects the effects of (1) presence and motion of the other body during the approach phase and the collision process and (2) free-surface wave generation. The first effects can be relevant for the relative motion of the ice

and the structure, and the second ones will lead to time-varying wetted surfaces of the two bodies during the impact. This may have consequences on the accuracy of the fluid-ice-structure interaction depending on the time scale of the impact event and the involved geometric and kinematic conditions.

In reality, the added mass coefficient depends on the acceleration and the oscillation frequency and possibly on the proximity of a neighboring body. The acceleration in term depends on the collision force level and the temporal variation and duration. It has been shown in several studies that the added mass varies significantly during the approach and the contact.

Motora et al. (1971) conducted a series of model tests and concluded that Minorsky's assumption of constant added mass is only reasonable when the duration of the collision was very short. For collisions with longer durations, the value of the added mass increases and can reach a value that is equal to or even greater than the ship's own mass. Isaacson and Cheung (1988b) investigated the added mass of an ice mass and found that it varied dramatically as the separation distance between the ice and the large offshore structure decreased. For instance, the added mass coefficient of the ice increased from its far-field value of 1.0 to a value of 1.6 at contact, in which the structure diameter was twice the iceberg diameter and both of them were assumed as circular cylinders.

To get more accurate impact energy and impact load, several researchers have turned to use advanced fluid-structure interaction (FSI) methods such as computational fluid dynamics (CFD), arbitrary Lagrangian-Eulerian (ALE) method, smoothed-particle hydrodynamics (SPH), and other simplified fluid dynamical simulation methods, in which the hydrodynamic effects are directly estimated within the solution algorithm.

Chander et al. (2015) carried out experimental and numerical studies to investigate the mechanics of ice loads caused by submerged ice blocks colliding. In the numerical study, the CFD model was used to include the hydrodynamic effects. The displacement and velocity of the numerical simulations agreed well with the experimental data. Different hydrodynamic forces acting during

the collision were investigated. The results indicated that added mass plays an important role during the underwater ice collision. The added mass increased suddenly prior to impact and reached the maximum at the time of impact. Tsarau et al. (2015) developed an approach to analyzing ice motions on upstream and downstream of the structure, in which a potential flow model was employed to predict the ice motion upstream of the structure, and a vortex element method was applied to the other situation. The results indicated the importance of including hydrodynamic models in simulation for analyzing ice-structure interactions.

Currently, the ALE method is most frequently used to analyze ship-ship and ice-structure interactions in which the FSI is explicitly considered. To solve the water-structure interaction problem, a Lagrangian formulation is adopted for the structural materials, and an ALE formulation is adopted for the water. In addition, with both Lagrangian and ALE formulations, a contact type algorithm is used to handle the coupling between the water and the structure's materials. Several research articles have presented results of FSI-based simulations that use LS-DYNA's ALE formulation. Wang and Derradji-Aouat (2010) calculated hydrodynamic loads and ship-ice interaction loads based on the FSI method, in which the wave maker simulation showed the good FSI results with regard to wavelength comparison. However, the ship and the ice were treated as rigid bodies in the collision model, which decreases the reality and accuracy with respect to prediction of structural damage. Gagnon and Derradji-Aouat (2006) conducted an ALE simulation of a ship colliding with bergy bits and got good agreement with the experiment with regard to the sway motion. Gagnon and Wang (2012) conducted numerical simulations of a collision between a loaded tanker and a bergy bit, in which hydrodynamics through LS-DYNA's ALE formulation and a validated crushable foam ice model were incorporated. Figure 4 shows the ship-iceberg collision model. It was observed that the movement of the bergy bit due to the vessel's bow wave prior to contact with the ice was realistic. Loads obtained by the simulation

Fluid Effects During Iceberg-Structure Interactions, Fig. 4

Full view of collision simulation components (Gagnon and Wang 2012)

compared reasonably well with measurements from the lab tests. All of these works were conducted in calm water. There is a lack of knowledge in wave effects on ice-structure interactions. In the near future, this problem may get more attentions due to the increasing interest in shipping in the Arctic.

Conclusions

When ice masses impact against fixed or floating structures, pronounced hydrodynamic forces are induced and cannot be ignored in the analysis of ice-structure interactions. It is clear that the hydrodynamic forces have significant effects on the impact velocity and the added mass of the impact bodies or impact trajectory during the approach and the collision. Thus, the hydrodynamic effects should be taken into account when estimating the collision response with regard to collision energy and impact load for ice-structure interactions. Although several studies have focused on the hydrodynamic effects in the far-field, the near-field, and the contact phase, the understanding of wave effects during ice-structure interactions, changing added mass coefficients, reduction of impact velocity, fluid boundary layer effects, viscosity effects, damping effects, and wetted surface effects, is still incomplete. Due to these limitations, further studies in this area through analytical, numerical, and experimental methods are needed.

Definition

Stiffeners, such as longitudinals and frames, are important structural members to support the hull plates in ship structures. They are mainly fabricated by flat, angle, bulb flat and T-shaped bars, etc. Among them, the bending work of frames is

the largest, so this section takes the bending process of frames as an example to discuss.

Introduction

Frame Bending Method and Its Classification

There are many methods to bend the frame, and the typical methods are listed as follows.

(1) Hot Bending by Hand

The heat bending procedure is a widely used technique to obtain curvature in steel frame and plates for shipbuilding purposes. It is a process that relied on highly skilled personnel and did not guarantee constant accuracy of shapes formed. Heat is applied in a line to the web surface of a frame by a flame torch, and then immediate cooling is obtained by air or water. Heat bending can be more time-consuming than using presses.

(2) Cool Bending with Equipment

Its principle is that load is applied on the frame by equipment, such as frame bender. When the load exceeds the yield strength of the material, the frame will be plastic deformed. By controlling the plastic deformation, the profile can obtain the desired shape.

The common equipment in shipbuilding production is cold frame bender, and some enterprises use profile straightening machine to bend the frame.

(3) Hot Bending with Equipment

In production, the frames are preheated and then bent by equipment. Sometimes, heat treatment is carried out simultaneously according to the characteristics of the frame materials. This method is often used in the processing of frame of special material.

The bending methods are usually related to the following factors: temperature, feeding mode, stress characteristics of frame in the process, etc.

(1) Temperature

According to whether the frame is preheated or not in frame processing, it can be divided into cold bending and hot bending.

Cold bending is the processing of bending frame at normal temperature. Hot bending process is to heat the profile above the recrystallization temperature of the frame material, and then apply external force to bend it into the desired shape.

(2) Frame-Feeding Method

The feeding mode of profile during processing usually includes continuous feeding and step-by-step feeding. Continuous feeding method is more suitable for parts whose curvature is constant, such as parts with circle shape.

(3) Stress State of Frame in Bending Process

According to the stress state of profile processing, it can be divided into three categories, including tension-bending principle, concentrated force bending principle, and pure bending principle.

The cold frame bender based on the principle of tension-bending principle is relatively rare. Its main advantage is that there is no compressive stress in the process of bending, so the possibility of wrinkling in the frame is small.

It is a traditional method to bend frames with the principle of concentrated force bending method. At present, most cold frame benders apply this bending principle. Because there are three stress points, it is also called three-fulcrum bending method. As shown in Fig. 1, shear force Q and bending moment M are generated by concentrated load P . At present, most of the cold frame bender used in shipbuilding are designed and manufactured according to the principle of concentrated force bending.

The principle of pure bending method is different from that of concentrated force bending method. The pure bending in mechanics refers to the plane bending state of a section of beam which is only subjected to bending moment but not to shear force. In order to obtain the pure bending condition of the beam, the method of material mechanics is to make the simply supported beam bear two equal concentrated loads symmetrically, and make the beam bending in plane. As shown in Fig. 2, the force acting on the beam under pure bending is shown. The moment at any section of

Forming Technology of Profiles, Fig. 1 Force situation of the method of concentrated force bending method. (a) Force diagram; (b) shear force diagram; (c) bending moment

Forming Technology of Profiles, Fig. 2 Force situation of the principle of pure bending method i. (a) Force diagram; (b) shear force diagram; (c) bending moment

the beam between the two concentrated loads is $M=Pa$, while the shear force $Q=0$, so the beam is in pure bending state.

Cold Bending of Frame Parts

At present, curved frame parts in commercial ships are fabricated generally by concentrated force bending principle, and the frames are bent along the longitudinal direction step by step. Following is a brief introduction to the most typical

Forming Technology of Profiles, Fig. 3 Diagram of the working part of the bender

cold frame bender and several technical problems in cold bending process.

Cold Frame Bender with Three Fulcrum

Figure 3 shows a diagram of the working part of the bender. In the bender, the central and two side molds are used as clampers in the bending process. In the working process, the central mold moves forward or backward so the load is applied on the frame, and both side clampers revolve around their respective axes. The frames are bent along the longitudinal direction step by step, i.e., the work is moved intermittently past the clamp which is held in place and actuated by a press. During the process, the central mold and the frame web are in the state of “clip and not tight” to avoid the buckling for concave shape forming. The side clampers clip the frame web tightly when the load is applied. This kind of bender has many advantages and is widely used.

Several Technical Problems in Cold Bending Process

Detection and Control of Shaping

In order to bend the frame to the web edge in accordance with the required curvature, the cold frame bender needs to be checked and measured along the forming line repeatedly in the process, so a certain

method of detecting and controlling the forming process is needed. For cold frame bender without NC control function, there are several methods to control the bending process.

(1) Artificial Sampling with Iron Samples (or Templates)

In the process of frame bending, the iron sample or template must be used repeatedly to check the web edge shape of the bended frame to see if it is consistent with the profile of the iron sample or template. This method not only needs to make iron samples or templates and labor-consuming material, but also is quite complicated and requires high technical level of workers.

(2) Inverse Curve

Obtaining the correct frame curvature can be achieved by the “inverse curve” method. The inverse line in frame bending refers to a special line, as shown in Fig. 4. The inverse curve is drawn in chalk on the web of straight frame, and the frame is bent until the curve becomes straight on the curved frame. In this way, in the process of frame bending, the formation of frame can be controlled by continuously detecting whether the curve is straight or not. Accurate calculation of this curve on the straight frame before bending is the key to control frame bending by this method. Now in shipbuilding, the inverse curve information can be determined for each frame by the loftsman using a CAD/CAM system.

Forming Technology of Profiles, Fig. 4 Diagram of the inverse curve bending principle. (a) Chalk line on the straight frame; (b) chalk line becomes straight on the curved frame

For the frames with longer length or larger curvature, it is sometimes necessary to divide the profile into several parts along the length, each part drawing an inverse line separately, and each inverse line should intersect a certain length. This bending control method is mainly suitable for frame with high web and small curvature radius.

The main advantage of this method is that it can save the material and time to make the template, but it needs to calculate and draw the inverse line, and the detection of frame processing is also complicated.

Lateral Deformation and Its Elimination Measures

The lateral deformation refers to the deformation in the direction of web thickness. As shown in Fig. 5, because the section of the frame (angle steel or bulb) is not symmetrical to the XOY plane, when the frame is bent by the moment M_z in the XOY plane, moments of stresses to Y-axis are unbalanced in the cross section; thus, another bending moment M_y on the XOZ plane is generated, which will cause the frame to deform on the XOZ plane (i.e., in the direction of web thickness), which is called lateral deformation.

In order to produce structural parts that meet the quality requirements, methods must be adopted to eliminate lateral deformation in the process of bending.

Springback and Its Treatment in Frame Cold Bending

Plastic deformation occurs in the cold bending process of frame, and it is accompanied by elastic

Forming Technology of Profiles, Fig. 5 Causes of lateral deformation

deformation. The recovery of elastic deformation after removal of external forces is called springback, which is the inherent characteristic of elastic-plastic materials. Springback has a negative impact on the cold bending process. How to deal with this factor correctly is very important to improve the efficiency and quality of cold bending of frames.

There are two ways to deal with it. One is to calculate the springback value in advance by theoretical calculation, and then superimpose it on the bending control quantity to bend the frame excessively, so that the frame can get the correct shape after springback. However, due to the inconsistency of material properties and the approximate simplification of mechanical model in calculation, the calculation results will be different from the actual situation, which makes the shape of frame formed difficult to achieve the desired results.

Another method is to measure the actual springback value after each bending action, and then bend the frame excessively according to the measure data. After repeating several times, the shape of the frame bended meets the design requirements.

Control Method of NC Cold Frame Bending

At present, the cold frame bender used in ship-building has realized numerical control (Li et al. 2008), and the control of frame bending is no longer dependent on iron sample, template, or inverse line. The main methods of forming control are endpoint measurement and chord measurement.

Principle of the Forming Control Based on Measurement of Locus of End Point

The key of this method (Shama and Miller 1967) is to control the end point of the frame and make it move in a specific trajectory in the bending process, so as to bend the straight frame into the part with the desired shape. The trajectory is determined by the shape of frame part uniquely.

Forming Technology of Profiles, Fig. 6 Diagram of series of points on the shape of the frame

As shown in Fig. 6, the shape of the frame will be specified as a series of coordinates at discrete intervals on the frame flange according to feed length. Ideally, these coordinates, together with the correct slope and curvature at each point, should be calculated exactly.

The position of the end point with respect to point C, at any bending operation (see Fig. 7), will be called the locus of the end point. Point C corresponds to the midspan of the current processing frame section. The end point position could be defined by the distance X along the tangent at point C and the distance Y along the normal from the end point. In bending process, as long as the X and Y of each processing section are controlled so that they can meet the required values, the straight frame can be bent into the required shape of the frame parts.

Principle of the Bowstring Measuring Method

The control model, called “bowstring measuring method” (Wang and Xu 1988, Li et al. 2008) that was originated by WHUT (Wuhan University of Technology), has been successfully applied in full-scale CNC frame benders.

Principle of Bend Control

As shown in Fig. 8, the shape of the frame will be specified as a series of points $P_i (i = 1, 2, \dots, n)$ at discrete intervals on the frame flange according to feed length. Point P_0 is a reference point for forming control in process. In this method, P_0 is on the reverse direction along the tangent to the

Forming Technology of Profiles, Fig. 7 Diagram of principle of measurement of locus of end point

Forming Technology of Profiles, Fig. 8 Diagram of principle of bowstring measuring method

frame at the first point P_i of the shape line of the frame part, and the distance between P_0 and P_i is L_0 which is determined by the structural dimension of the bender. The frame section between P_i and P_{i+1} is the current section in bending. The control principle is to use three elements of triangle $P_0P_iP_{i+1}$ as variables to control the profile forming. As shown in Fig. 8, the segment, which

will be formed between point 2 and point 3, is illustrated. Point 2 and point 3 are the two vertices of the triangle.

The first side length, L_i , is the distance between two vertices P_0 and P_i . The second length, S_0 , is the value of the distance between the two vertices P_i and P_{i+1} . The angle, θ_i , is that between the radial line and the bowstring, in respect to the

current forming section. L_i is used as the control parameter for feeding, and θ_i is used for shape-forming control. L_i and θ_i can be calculated with the formula as follows:

$$L_i = \sqrt{(x_0 - x_i)^2 + (y_0 - y_i)^2} \quad (1)$$

$$\theta_i = \cos^{-1} \frac{L_{i+1}^2 - L_i^2 - S_o^2}{2L_i S_o}$$

where (x_0, y_0) and (x_i, y_i) are the coordinate of point 0 and point i.

Control Method of Springback

The results of theoretical calculation by E.Н.Мошнин's formula for springback show that there is linear relationship between the bending curvature and curvature of springback. Although the calculation result was approximate, the change tendency of springback showed by the result is close to the right law. The control model of stepwise approximation control principle is proposed based on the rules (Wang 1984, Li et al. 2009). Stepwise approximation control is actually a trial and error method.

In the working condition of frame bending, the curvature of the frame shape formed is difficult to measure. So the amount of angle is measured and used as the control parameter in the control model of bowstring measuring method. When the trial

and error method was applied, the amount of angle of spring-backing in the bending process is added to the forming control parameter for the next forming operation for the same frame section. So, iterative operations are needed to achieve the correct shape. Of course the iterative operation will affect the efficiency of frame forming.

In the iterative operation, some times of the forming operation are needed for each working section of frame (see Fig. 9). In the first operation, the control parameter is θ_1 , and the amount of springback is T_1 after the load is released. The next bending operation is needed to be applied on the same working section because of the springback. And the amount of springback T_{j-1} ($j = 2, 3, 4, \dots$) is added to θ_1 for the next forming operation. By this iterative way, bending is applied until an acceptable shape is achieved. The control angle in the iterative process is:

$$\theta_j = \theta_1 + T_{j-1} \quad (2)$$

After the load is released in the first operation, the difference between the plastic deformation and the control parameter is the amount of springback, which is:

$$\Delta\theta_1 = T_1 \quad (3)$$

In each of the next bending operation, the difference between the plastic forming and

Forming Technology of Profiles, Fig. 9 Diagram of control model of trial and error method

the control parameter is $\Delta\theta_j$ for each operation $\Delta\theta_j$ is

$$\begin{aligned}\Delta\theta_j &= (\theta_j - T_j) - \theta_1 \\ &= (\theta_1 + T_{j-1} - T_j) - \theta_1 \\ &= T_{j-1} - T_j\end{aligned}\quad (4)$$

When $|\Delta\theta_j| < \varepsilon$, an acceptable shape is achieved for the working portion. ε is the allowable deviation.

Definition

The steel hull plates for ship building are categorized into single curved plates and complex curved plates, among which the single curved plates are bent only in one direction, with a simple shape and a small bending degree, while the complex curved plates have a large bending degree and a complex line, including sail-shaped plates (Fig. 1), saddle-shaped plates, etc (Huang, 2013).

The forming technique of hull plate components mainly involves mechanical cold bending and line heating bending. Generally, single curved plates are processed through mechanical cold bending. Complex double curved plates are usually mechanically processed to form the curve in one direction by cold bending, and then processed to form the curve in the other direction by line heating. Besides, a few shipyards also process double curved plates through cold bending by hydraulic press machines or numerical-controlled bending press machines (Ji, 2005).

Introduction

Roll Bending Forming

Roll bending is the most commonly used method for plate cold bending, and the main equipment of roll bending includes three-roll bending machines (Fig. 2), four-roll bending machines (Fig. 3), etc., among which the three-roll bending machine is

Forming Technology of Steel Hull Plates, Fig. 1 Sail-shaped plate

the most widely used. The single curved plates (e.g., bilge strakes in parallel middle body) among the outer hull plates are usually formed by three-roll bending machines.

Forming Technology of Steel Hull Plates, Fig. 2 Three-roll bending machine

Forming Technology of Steel Hull Plates, Fig. 3 Four-roll bending machine

The lower shaft roller of ordinary three-roll plate bending machines is an active roller, installed in a fixed bearing and driven by an electric motor through a speed reducer to rotate, while the upper shaft roller is a driven roller, which can be adjusted up and down. When the shaft roller rotates, the plate is bent into a certain curved shape between the three rotating shaft rollers, as shown in Fig. 4.

The three-roll plate bending machine is categorized into open type and closed type. The frame on one end of the upper shaft roller of the open three-roll plate bending machine can be disassembled so as to take out the enclosed cylindrical component after bending, while the frame of the closed three-roll plate bending machine cannot be disassembled, so the enclosed cylindrical plate cannot be bent with it.

In order to improve the performance of bending plates, a three-roll bending machine, the three rollers of which are respectively adjustable up and down, could also be used and is suitable for the forming of simple curved plates. Moreover, a three-roll plate bending machine, the shaft roller of which is adjustable side to side, could be used to make closed cylindrical barrel and cone. For the four-roll plate bending machine, its two side rollers could form two pairs of asymmetric three-core rollers with the upper and lower rollers respectively, which can not only minimize the remaining right-angle sides of the workpieces, thus skipping the prebending procedure, but also eliminate the need to turn the work-piece around. The four-roll plate bending machine is of excellent performance and high efficiency but has complex structure, complex control, large weight, and high cost (Liu et al. 2011).

Forming Technology of Steel Hull Plates, Fig. 4 Working diagram of three-roll plate bending machine

In addition, the three-dimensional curved surface flexible roll forming technology is a new plate roll bending forming technology developed in recent years. Its basic principle is as follows: First, the required curve is composed of several short rollers with adjustable heights, which can rotate and swing on their own; second, the three-dimensional curved surface continuous local plastic forming is realized through the pressure of the short rollers and the friction between the short rollers and the plate.

According to the different shapes of the workpieces, the position of the short rollers can be adjusted to form the curvature required for forming the workpieces, so as to realize multipurposes by one machine. Flexible roll forming technology is a combination of multipoint forming technology and traditional roll bending forming technology, which has the characteristics of high efficiency, low cost, flexibility, and continuity. At present, the research on this technology gradually becomes mature, and the experimental device has been developed, as shown in Fig. 5.

Buckling Forming

Buckling forming is another plate bending method based mainly on cold processing. The main equipment used in this method is the

hydraulic press machine and the multiple-use plate bending machine, the latter of which is used by some shipyards. In recent years, with the development of numerical control technology, numerical-controlled bending press has already been developed (Xu, 2005).

Hydraulic Press Machine

Hydraulic press machine is a cold bending equipment which bends and forms the plate using the liquid pressure. The machine uses liquid as the working medium and achieves a variety of processes according to its mechanism of energy transmission based on the principle of Pascal. The hydraulic press machines are generally composed of the machine (main engine), the power system, and the hydraulic control system. According to different liquid media used, there are oil hydraulic press and water hydraulic press, among which the oil hydraulic press is more widely used. The pressure of the oil hydraulic press is produced by the oil pump, and since there is generally no pressure storage device, the oil hydraulic press is relatively light and simple structured, while the water hydraulic press is usually equipped with pressure storage device, so it can produce greater pressure, but is huge and complex structured.

When the hydraulic press machine is performing buckling, the compression module must be installed on the press head to ensure the shape of the plate. The compression module can be divided into general type and special type according to its application scope. The general compression module can bend plates with different surface shapes. If the number of components with the same shape is large, the special compression module could be produced.

Hydraulic press machines can not only bend hull components of different shapes, but also perform plate flanging, angle pressing, prebending, leveling, etc.

Compared with the traditional technique, this hydraulic forming process has obvious technical and economic advantages in reducing weight, reducing the number of parts and molding dies, and reducing production costs and has been

Forming Technology of Steel Hull Plates,
Fig. 5 Experimental device of 3D curved plate flexible roll forming

more and more widely applied in the industrial field.

Numerical-Controlled Bending Press

The application of numerical control (NC) automatic processing technology to plate forming can not only greatly improve the production efficiency of plate bending and reduce labor intensity, but also improve the accuracy of bending, thereby reducing the workload of assembly and rectification. The use of this technology with other NC processing devices could realize the comprehensive mechanization and automation of hull processing workshop, and improve the comprehensive production capacity. The research on numerical-controlled bending press has been paid great attention to both in China and abroad for many years. Figure 6 shows the prototype of the multihead 3D numerical-controlled bending press, jointly developed by Wuhan University of Technology and Shandong Shuoli Machinery Manufacturing Co., Ltd. Before bending, the press heads of the former block (or force plug) are automatically adjusted one by one by NC program, so as to change the heights of them and form a surface of the same shape as the required component (springback within consideration). When the plate to be bent is well positioned, the heads of the upper molds (or lower molds) fall (or rise), and the plate is bent into various shapes required (Qiyang et al. 2017).

Forming Technology of Steel Hull Plates,
Fig. 6 Multihead 3D numerical-controlled bending press

Line Heating Bending

The line heating bending is currently the most widely used double curved shell plate processing technology in shipyards at home and abroad. More than 90% of the hull shell plates with complicated curvature can be processed by this technique (Song et al. 2016).

The line heating bending is a thermal forming process, which uses a heat source (such as gas flame, high-frequency inductance, laser heat source, etc.) to move along a predetermined heating line at a uniform or varying speed on the surface of the metal plate, and to perform the local line heating. As shown in Fig. 7, a certain temperature distribution is generated on the surface and the thickness direction of the plate. A certain part of the metal plate is heated and expanded and is hindered by the surrounding cold metal, so the plastic deformation is generated in the process of such mutual interaction. Then water is used to cool the metal in a certain distance behind the heat source. The plastic deformation could cause the heated and expanded metal to begin to shrink and stretch when facing coldness, thus resulting in local deformation of the metal plate, as shown in Fig. 8. This local deformation is due to the angular deformation on the surface and along the thickness of the plate, which is the basis for the forming of the whole metal plate (Li et al. 2006).

Experienced workers often estimate (based on their previous experience) the required shrinkage needed for each part (often divided by the frame space), by observing the overall shape of the curved plate (taking the template guideline as a reference), and then further consider the way to arrange the heating lines and determine other process parameters. At the same time, during processing, it is also necessary for them to continuously examine the differences between the generated shape and the target shape, and timely modify the layout of the heating lines and other processing parameters.

The line heating bending process is a complex thermo-elastic-plastic deformation process, which is affected by many factors. The key to

Forming Technology of Steel Hull Plates, Fig. 7 Schematic diagram of line heating bending process

Forming Technology of Steel Hull Plates, Fig. 8 Schematic diagram of line heating bending deformation

the application research of line heating bending is to find out the influence law of various factors that influence steel plate forming effect during the line heating process (Zhang et al. 2011). First, it is necessary to determine the main process parameters of line heating deformation. The influencing parameters, according to their influence weight, can be generally divided into two categories: The first category is the most important influencing factors, such as the layout of the heating lines, heating speed, heating line length, heating line distance, heat source, distance from the nozzle to the plate surface, the initial shape of the plate (length, width, thickness, curvature, etc.) and initial stress, cooling rate, steel plate support mode (free ends, supported ends, and supported four corners), etc.; the second category is the secondary important influencing factors, such as air temperature, pressure and flow rate of oxygen, pressure and flow rate of acetylene, water flow rate, and the texture of the steel plate. The influence of main process parameters on forming effect generally includes the following:

The Influence of Heating Line Layout on Forming Effect

During the line heating bending, the correct layout of the heating wire is directly related to the correct deformation of the steel plate. The line heating at different positions on the same steel plate will cause completely different forming shapes. Most hull shell plates can be divided into sail-shaped plates and saddle-shaped plates, and the forming of both plates involves first forming the transverse curve through cold bending (due to its large curvature) and then forming the longitudinal curve through line heating bending. There are also differences in forming the two plates. Because the direction of the longitudinal curve of the sail-shaped plate is the same as that of the transverse curve (i.e., both are bent toward one side of the plate), the heating lines are positioned on both sides of the cross section of the plate (Fig. 9). During its bending, the method of line heating closing is used to shorten the longitudinal edges on both sides of the component to obtain the longitudinal strength. However, because the direction of the longitudinal strength of the

Forming Technology of Steel Hull Plates, Fig. 9 Sail-shaped plate and heating line layout

Forming Technology of Steel Hull Plates, Fig. 10 Saddle-shaped plate and heating line layout

saddle-shaped plate is opposite to its transverse strength (i.e., the transverse curve is bent toward one side of the plate, while the longitudinal curve is bent toward the other side), the heating lines are positioned in the middle of the cross section of the plate (Fig. 10). During bending, the middle part of the back of the component should be heated to shorten the middle part longitudinally to obtain the longitudinal strength.

The Influence of Heating Speed on Forming Effect

With all the other processing conditions remaining the same, the lower the heating speed is, the greater the deformation of the steel plate near the heating line will be. It should be noted that the lower the heating speed is, the higher the surface temperature of the steel plate will be. Too high temperature could easily damage the texture of the steel plate, especially that of the thin steel plate, and the plate could be even burnt through. On the contrary, if the heating speed is too high, the surface temperature of the steel plate will be

low, and it is often unable to deform the steel plate, especially the thick steel plate which requires a higher temperature. Therefore, steel plates of different thickness require different heating speed. Generally, for a thin steel plate, a higher heating speed could form a greater deformation, while for a thick steel plate, only a lower heating speed could form a certain deformation (Bae et al. 2013).

The Influence of Heating Line Length on Forming Effect

Generally, the longer the heating line is, the greater the deformation of the steel plate will be. In the real processing, it should be noted that the length of the heating line is also related to the plate width. For the sail-shaped plate, the heating lines are arranged on the edge of the plate, the length of which should not surpass the neutral axis of the cross section, so as to guarantee the forming, and the line could not be too short, either. The heating lines of the saddle-shaped plate are arranged in the middle of the plate, and multiple heating lines could be arranged on the same flame path, and the length of the heating lines should be moderate.

The Influence of Steel Plate Thickness on Forming Effect

With all the other heating conditions remaining the same, the thicker the steel plate is, the more difficult it will be to form steel plate deformation, the greater will be the energy required for deformation of steel plate, and the smaller will be the deformation generated near the heating line (Zayed et al. 2018).

The Influence of Heating Sequence on Forming Effect

For the saddle-shaped plate, the heating lines are arranged in the middle of the plate, and multiple heating lines are often arranged on the same flame path. The heating sequence of these heating lines has a certain effect on the local shrinkage. However, for the sail-shaped plate, such problems do not exist. The influence of the heating sequence on the deformation of the steel plate is mainly manifested in the obvious distinction between

deformations generated by the initial heating line and those by the other lines on the same flame path. With all the other heating conditions remaining the same, the deformation generated by the initial heating line is smaller than those by the other heating lines (Iranmanesh et al. 2014).

In a word, the line heating bending technique is one of the most widely used bending techniques in shipyards. In addition, the line heating bending technique can also be used to level and straighten the welding deformation, such as T-beam welding deformation, plate frame welding deformation, etc. which is generally known as the rectification by flame heating and water cooling, with its principle, influencing factors and process parameters similar to the line heating plate bending.

However, the line heating bending process also has serious defects. First, there are many factors that could influence the forming, thus causing the forming laws difficult to master. At present, the forming mainly relies on manual operation by workers based on experience, and it is difficult to achieve mechanization and automation. Second, its low efficiency could not meet the needs of modern shipbuilding. Therefore, numerical control line heating bending is being studied at home and abroad, in order to achieve the automation of plate forming, improve labor productivity, reduce labor intensity, and completely reform the manual operation. Figure 11 shows the line heating automation system IHI- α , jointly developed by Ishikawajima-Harima Heavy Industries (IHI) and the Welding Research Institute of Osaka University. It is an automatic line heating forming system for the hull shell plates using high frequency heating as the heat source. Fig. 12 shows the prototype of the large and complex curved surface steel plate line heating forming robot, successfully developed through the cooperation of Dalian University of Technology with Dalian Shipbuilding Industry co., ltd. The robot could be integrated with the process parameter prediction software system to achieve the automatic forming of sail-shaped plates and saddle-shaped plates as hull shell plates.

FPSO

Ke Zhou
Shanghai Jiao Tong University, Shanghai, China

Synonyms

FPSO (floating production storage and offloading); SPM (single-point mooring)

Definition

A *floating production storage and offloading (FPSO)* unit is a floating vessel used by the offshore oil and gas industry for the production and processing of hydrocarbons and for the storage of oil. A *FPSO* vessel is designed to receive hydrocarbons produced by itself or from nearby platforms or subsea template, process them, and store oil until it can be offloaded onto a tanker or, less frequently, transported through a pipeline. *FPSOs* are preferred in frontier offshore regions as they are easy to install and do not require a local pipeline infrastructure to export oil. *FPSOs* can be a conversion of an oil tanker or can be a vessel built specially for the application. A vessel used only to store oil (without processing it) is referred to as a floating storage and offloading (*FSO*)

vessel (https://en.wikipedia.org/wiki/Floating_production_storage_and_offloading).

Introduction

A floating production storage and offloading (FPSO) is a floating facility, usually equipped with hydrocarbon processing equipment for separation and treatment of crude oil, water, and gases, arriving on board from subsea oil wells through flexible pipelines. FPSOs have storage capacity for the treated crude oil produced and are equipped with the offloading system to transfer the crude oil to shuttle tankers for shipment to refineries.

FPSOs are also called as floating oil processing factories on seas. Their displacements cover a range from 50 thousand to 300 thousand tons, with the deck area as large as 2–3 football fields. FPSOs can be a conversion of an oil tanker or can be a vessel built specially for the application, as Fig. 1. One of the advantages of FPSOs is that they are particularly effective in remote or deepwater locations, where seabed pipelines are not cost-effective. FPSOs eliminate the need to lay expensive long-distance pipelines from the processing facility to an onshore terminal. Once the field is depleted, the FPSO can be flexibly moved to a new location.

FPSOs have been widely used in oil exploitation around the world with a concentration in West Africa and South America, as shown in Fig. 2 (OilMooc 2011). As of August 2015, there are more than 277 floating production units in use around the world, of which 62% are FPSOs (“Available FPU count at all-time high,” 2013).

History

The first oil FPSO was the *Shell Castellon*, built in Spain in 1977 (Mohamed A. El-Reedy, 2012). Today, over 270 vessels are deployed worldwide as oil FPSOs, as shown in Fig. 3 (Offshore Magazine 2016). For the production ability, most FPSOs are rated for 7000 bbl/d to 250,000 bbl/d, with a storage of 24,000 to 2,200,000 bbl. They can operate with up to 163 subsea wells and 80 risers. Now, the FPSO operating in the deepest

FPSO, Fig. 1 Illustration of a FPSO in operation

FPSO, Fig. 2 Distribution of FPSOs worldwide

waters is the FPSO *Turritella* designed by SBM, which is owned by Shell and moored at a depth of 2896 m in the US Gulf of Mexico (First Oil for *Turritella* 2016).

The development of FPSO worldwide generally has experienced four periods:

1. 1976–1985 was the early stage of development, during which the single-point mooring system enabled FPSOs to be an effective offshore oil and gas exploitation facility.
2. 1986–1994 was the growth period of this technique, during which FPSOs were widely adopted in stranded oil fields worldwide, with an increase of more than two vessels per year on average.
3. 1995–1998 was the period of expansion, during which the number of FPSOs exploded rapidly, with an increase of more than eight vessels per year on average.
4. 1999–now is the flourishing period, during which some outstanding breakthroughs have been achieved to increase the operation water depth from several hundred meters to over one thousand meters. Especially after 2002, different facilities of offshore oil and gas exploitation have been developed in multiple forms, including LNGFPSO, FPDSON, and LPGFPSO.

Over the 40 years, the first 10 years witnessed the birth of this novel concept and its industrial application. In the following 20 years, this

FPSO, Fig. 3 Distribution of FPSOs worldwide (by 2015, cited from Offshore Magazine)

technique experienced a steady development and wide application. In the recent 10 years, the number of FPSO increased sharply, with a broad application in different fields of engineering.

FPSO Structure

Normally, a FPSO system consists of five components, including the hull, topside modulus, turret, mooring system, and turret.

FPSOs can be divided into three types according to their hull shapes, which are ship-type, multi-body-type, and cylinder-type, as shown in Fig. 4. At present, ship-type FPSOs are the most dominating type used in exploitation that were either newly built or converted from available oil tankers (Fig. 5).

Topside modulus is the core part of FPSOs. Compared with conventional oil tankers, FPSOs'

topsides include some additional modulus, such as production and process module, flare tower, special offloading system, and helicopter platform. The appropriate arrangement of all the modulus in the limited area is of great significance. The following picture shows the layout of the topsides of a FPSO.

Mooring systems are used to constrain the motion of large FPSOs in open seas, through connecting the subsea anchor piles and the vessels with mooring lines made of steel or polyester fiber. There are normally two types of mooring systems used prevalingly, which are single-point mooring and spreading mooring. Single-point mooring system is employed by most ship-type FPSOs in the world due to its weather vane function which can alleviate the environmental loads effectively. Spreading mooring system is employed mostly on cylinder-type FPSO and those ship-type FPSOs in some special ocean

FPSO, Fig. 4 Three types of FPSO. (a) Ship-type. (b) Multi-body-type. (c) Cylinder-type

FPSO, Fig. 5 Topside structure of FPSO

areas whose environmental loads are kept at low-level or have dominating directions all over the year, for instance, Western Africa and oceans near equator.

One of the most important and cost parts of FPSO system is the turret. Turret is a compact and multifunctional structure that integrates the mooring lines, risers, and FPSO hull. FPSO's turret has two forms as inner and external turret. Internal turret enables the hull protecting the turret well, so newly built FPSOs often adopt internal turret design. On the contrary, external turret has no hull protection so the wave slamming problem has to be taken into consideration, but external turret design is often used for converted FPSO because external turret can be added directly at the vessel bow (Zhao et al. 2013).

FPSO Hydrodynamic Performances

To study the hydrodynamic performances of FPSO systems coupled with mooring and riser systems, both numerical and experimental methods have been adopted by the engineers

(Fig. 6). In addition, model tests in wave basin are also implemented to validate and modify the numerical models.

Numerically, the hydrodynamic information of FPSO can be predicted based on the three-dimensional potential flow theory. The added mass coefficients, radiation damping coefficients, and the first-order response amplitude operators (RAO) of the wave forces and motion responses can be calculated in frequency domain. Further, time domain analysis is applied to calculate the integrated six-degree of freedom motion (Fig. 7) of the FPSO coupled with its mooring system.

FPSOs of ship-type have special hydrodynamic performances due to the coupling effect between hull shape and mooring system. Firstly, strong vertical plane motion would be induced, namely, the heave, roll, and pitch motions, due to the superposition of their natural frequencies with the wave-dominating frequencies. In addition, FPSOs with single-point mooring (SPM) might suffer from large wave slamming loads on bows because of the weather vane effects (Fig. 8).

Secondly, FPSOs also experiences considerable horizontal plane motions, such as surge,

FPSO, Fig. 6 Topside structure of FPSO. (a) Numerical simulation. (b) Model test

FPSO, Fig. 7 Six-degree of freedom ship motion

FPSO, Fig. 8 Weather vane effect of SPM

sway, and yaw. Apart from the first-order motions under irregular waves, slow drift motions on the horizontal plane are also highly concerned because long natural periods of the mooring system could give rise to the motion resonances induced by second-order wave forces. Hence, the safety of mooring lines needs to consider second-order wave forces.

Thirdly, the ship-shaped FPSOs have small roll damping. Thus, strong roll motions would be simulated under oblique waves which will inflict

discomfort of the crew members. Equipment-like bilge keel and anti-rolling tanks have been developed to mitigate violent roll motions of FPSOs.

FPSO Mooring System and Risers

As an important part of FPSO system, mooring system serves to prevent vessels being drifted away by low-frequency components of irregular waves and keep the vessel in a certain heading

against the dominant environment. Besides, the mooring system can also be combined with a fluid transfer system that enables connection of (subsea) pipelines to the tanker. Generally, mooring systems can be divided into two types—spread mooring system and single-point mooring systems (SPM). SPMs can be further divided as the internal turret, the external turret, and the soft yoke wishbone configuration. Figure 9 demonstrates all four kinds of mooring systems.

Risers are important parts of FPSO systems that connect floaters and subsea production

units. As a kind of ship-type floating structure, FPSOs have poor hydrodynamic performances in heave and pitch modes due to the large water-plane area, which brings great challenges to the stiffness and fatigue analysis of risers attached. Besides, the large tension of upper part of risers connected with the floating terminal calls for a higher design standard of FPSO hull structures.

According to their structures and applications, three kinds of deepwater risers (see Fig. 10) are quite applicable for FPSOs, namely, steel catenary

F

FPSO, Fig. 10 Deepwater riser systems. (a) SCR. (b) TTR. (c) HTR

riser (SCR), top tension riser (TTR), and hybrid tower riser (HTR).

Green Water Effect

FPSOs with single-point mooring (SPM) system is vulnerable to huge slamming waves on ship bows due to the weather vane effect, causing large amounts of water shipped onto the deck. This phenomenon is defined as green water (see Fig. 11) that will cause violent impact and destruction of important equipment on the bow area of FPSO, such as internal turret, risers, and pipelines. Thus, the consideration of green water events on FPSO is of great significance to ship structures, hydrodynamic performances, and production safety during the process of design.

Green water event is a problem of fluid-structure interaction between highly nonlinear waves and FPSO structures. The difficulty of prediction mainly focuses on the strong nonlinearity of wave fields and couplings between FPSO and waves.

FPSO, Fig. 11 An event of green water on deck

Early studies on green water are mainly based on model tests. Some pioneer studies were widely conducted on various aspects such as freeboard level, bow shape, and wave steepness. Two types of green water on deck were observed and categorized in tests (see Fig. 12). For practical purpose, some simplified methods were proposed afterward. For modeling green water on deck, flooding wave theory and dam-breaking model were applied. Shallow water theory was employed to represent water propagation on deck.

Recently, some high-accuracy methods have been developed to simulate the green water event based on computational fluid dynamic (CFD) methods. Many schemes, like VOF and level-set, have been used to capture the strong motions of nonlinear free surfaces and, thus, highly improve the prediction accuracy of wave loads on structures.

Tandem Offloading

The types of FPSO offloading system are basically as follows: pipeline offloading, tanker transportation, and offloading alongshore. Among all, the tanker transportation is mostly used in FPSO offloading. Oil is directly offloaded from FPSO to shuttle tanker or barge which transports the oil to shore. Tandem offloading is one of the classical and effective ways to transfer the oil from FPSO vessels to transport vessels (Fig. 13).

Tandem offloading operation is carried out in such a way that the transport vessel is located in the sheltered region behind FPSO connected by hawsers (at a distance of about 80 meters), while a side-by-side offloading operation is carried out in parallel positions. Compared with side-by-side

FPSO, Fig. 12 Two types of green water on deck. (a) Dam-breaking-type green water. (b) Wave-plunging-type green water

FPSO, Fig. 13 Tandem offloading

FPSO, Fig. 14 Single-point-moored (SPM) FPSO tandem offloading

FPSO, Fig. 15 Turret-moored FPSO tandem offloading

FPSO, Fig. 16 Spread-moored FPSO tandem offloading

mooring, tandem mooring can withstand more rigorous environmental conditions and is more advantageous in terms of fast disconnection. In addition, dynamic positioning (DP) can be applied to transport vessel in tandem offloading,

to eliminate the fatigue risks of mechanical restriction between two floaters.

For FPSOs of different mooring systems, three corresponding offloading scenarios are considered in Figs. 14, 15, and 16, where the black

lines are mooring lines and the brown lines are oil pipes.

The first one is the single-point mooring (SPM) offloading from a catenary anchor leg mooring (CALM) buoy or similar facility. The transport vessel can freely weather vane and assume a heading of “least” resistance relative to the prevailing weather. Beside the existing SPM systems in shallow water, they are nowadays planned as offloading facility in the neighborhood of FPSOs for deepwater fields.

The second one is the tandem offloading from a turret-moored FPSO. The transport vessel can still weather vane, but its behavior is influenced by and coupled to that of the FPSO. In benign and moderate environments, the transport vessel is typically a vessel and assisted by one or more tugs. Depending on their relative loading conditions and possible support by stern thrust or tugs, they will assume headings with respect to the environment. Besides the passive mooring with a bow hawser, DP tandem offloading is used at a number of locations especially in harsh environments.

The third one is tandem offloading from a spread-moored FPSO. The transport vessel is typically a vessel of convenience and assisted by one or several tugs. Such operations take place, e.g., offshore West Africa, where the prevailing environmental conditions are relatively benign compared to those of North Sea, the Gulf of Mexico, and South China Sea, but often characterized by

non-collinear swell, wind, local waves, and current conditions. Due to the “fixed” heading of the spread moored FPSO, the vessels do not both have the ability to assume freely a heading with respect to the environment. The behavior of the transport vessel is also heavily influenced by the presence of the FPSO (shielding, etc.).

Internal Turret

The mooring system of FPSO is an essential part of offshore exploration for providing station keeping of floating systems. With the offshore oil production moving into the deep sea, turret mooring systems (Fig. 17), as a single-point mooring configuration, have been the major facilities for the positioning of floating production unit in open seas.

The turret mooring system consists of a turret assembly that is integrated into a vessel and permanently fixed to the seabed by means of a mooring system. The turret system contains a bearing system that allows the vessel to rotate around the fixed geostatic part of the turret, which is attached to the mooring system.

The turret mooring system can also be combined with a fluid transfer system that enables connection of (subsea) pipelines to a FPSO (Bluewater 2019). The fluid transfer system includes risers between the pipeline end manifold

FPSO, Fig. 17 Turret mooring system (inner turret)

FPSO, Fig. 18 Illustration of two types of turret mooring systems. (a) External turret mooring system. (b) Internal turret mooring system

at the seabed and the geostatic part of the turret. In the turret a swivel provides the fluid transfer path between the geostatic part and the free weather vane FPSO that rotates around the turret. The turret system is fully passive and does not require active vessel heading control or active rotation systems in the turret. The turret systems can be divided into two types, which are located externally or internally with respect to the vessel hull structure (see Fig. 18).

Structure of the Internal Turret

The internal turret system is integrated into the hull structure at the bow of the vessel. The internal turret is a slender structure that is connected to the vessel structure via a large-diameter 3-race roller main bearing at the top and via a large-diameter sliding bearing at the bottom.

The slender turret shaft ensures that the horizontal loads from the risers and mooring lines are transferred via the sliding bearing to the vessel, while the remaining forces from the turret and the vertical loads from the risers and mooring lines are transferred via the 3-race roller bearing. The supports of the bearings are integrated into the turret casing, which is part of the modified vessel hull structure. Typically, the turret casing is a cylindrical structure that is integrated between the bottom and the deck of the vessel and transfers the turret loads via the vessel web frames to the vessel hull structures.

The turntable decks are positioned on top of the 3-race roller bearing. The turntables include

FPSO, Fig. 19 Structure of internal turret

the process facilities for commingling fluids from the risers using manifolds, as well as pigging facilities or chemical injection facilities to assure the flow in the risers. In addition, the turntables provide space for subsea control facilities, to enable safe operation of the subsea manifolds and wellheads. The highest deck level of the turntables provides space for the swivel stack, which transfers fluid and electrical power to the turret access structure that is located on the vessel main deck. This access structure also provides support access to the different turntable decks. Figure 19 shows the cross section of internal turret.

Main Characteristics of Internal Turret

The main advantages of the internal turret mooring production storage system are:

1. Compared with other types of single-point mooring systems, the internal turret mooring system is suitable for deeper water and more complex sea states.
2. The facilities of production, storage, oil loading and turret assembly, etc. are arranged concentratively on one ship. This arrangement makes the system get rid of connection module and become more compact. Hence the environmental forces and motion responses are minimized, and mooring performances are improved and the reliability of the system is raised.
3. Because the turret is located in the interior of the hull body, the hull body can protect the turret and pipelines from damage. It is also convenient for the management and maintenance of the turret assembly in complex sea state.
4. Low cost of installation, convenient maintenance, and flexible movement from one production site to another, almost all of the facilities onboard can be used after being moved to another site.

Nevertheless, some problems of internal turret mooring systems should be also mentioned.

1. The large-diameter opening in the hull body is unfavorable for the general arrangement and ship structure strength. Both the hull structure strength and the hull volume will be sacrificed.
2. The position of the internal turret has some negatively influence the weather vane capability of the single-point moored FPSO, compared to that of external turret.

Yoke Mooring System

FPSO has been widely applied to the world marine petroleum exploitation. Without its own dynamical system, it usually relies on the mooring

system as a positioning device to guarantee the safety of operation in a fixed area. As a kind of single-point mooring (SPM) system, soft yoke mooring system realizes FPSO weather vane effects by the multiple-hinge-point connection mode, and it has been widely applied to oil and gas exploitation in the shallow waters in Bohai Bay in China and the Gulf of Mexico (Lyu et al. 2017).

Compared with traditional internal and external turrets and other single-point mooring systems, the soft yoke single-point mooring system owns obvious technological advantages. It can realize vessel-mooring separation, satisfying a set of the mooring system applicable to multiple ship-type structures. It can realize repeated applications of the mooring system in multiple sea areas, which makes it easy to disassemble the whole mooring and its local components by hinge points. Meanwhile, the above water mooring mode of the soft yoke system avoids the direct contact between components and seawater and the impacts of sea ice in ice regions and reduces the influences of environmental corrosion and lengthens the service life (Fig. 20).

Widely applied in the 1980s, the soft yoke mooring system has drawn wide concern from global oil and gas companies. Multi-hinge soft yoke mooring system is considered as the currently best single-point mooring form and has been applied to oil and gas exploitation in shallow water areas (water depth of tens of meters).

Shallow FPSO Mooring Systems

As an important part of FPSO system, mooring system serves to prevent vessels being drifted away by low-frequency components of irregular waves and keep the vessel in a certain heading against the dominant environment. Generally, mooring systems can be divided into two types—spread mooring system and single-point mooring systems (SPM). SPMs can be further divided as the turret mooring and the soft yoke mooring configuration. Typically, in shallow water, a conventional spread mooring system will be used. In moderate water depth, spread mooring system may prove to be uneconomical and the motions may become unacceptable.

FPSO, Fig. 20 Soft yoke single-point mooring system and FPSO

F

FPSO, Fig. 21 Illustration of different kinds of mooring systems. (a) Spread mooring system. (b) Soft yoke SPM tower system

Hence, a system with a fixed structure (jacket) and a yoke arm link to the floating structure (soft yoke mooring system) may be found useful. Figure 21 demonstrates the two kinds of mooring systems.

Spread mooring systems are multipoint mooring systems that moor vessels to the seabed using multiple mooring lines. The mooring lines can be directly attached to the hull of the vessel as well as indirectly using buoys on the sea surface. When they are directly attached to the hull, structural modifications are required to provide strong points for the mooring lines.

The soft yoke mooring system includes a rigid steel frame that is connected to the tower by means of hinges and to the vessel by means of a pendulum structure. Typically, the pendulum structure includes two pendulums that provide a restoring force for the oscillating vessel. This restoring force maximizes the range of local environmental conditions in which the SPM system can moor a vessel.

Evolution of Yoke Mooring System

The soft yoke mooring system is developed on the basis of a single anchor leg mooring system (SALM), which is like a large buoy floating on the sea (Fig. 22a), with the lower end on the sea bottom and the upper end connected to the ship bow. This firstly appeared in 1969, and then, the lower part of buoy evolved into a cylinder-type buoyancy tank directly fixed on the bottom of the sea (Fig. 22b). This can reduce the motion radius of the FPSO and prevent the buoy from causing damage to itself and other related equipment when heaving up and down with waves.

After further development, the mooring lines attached to the ship bow gradually evolved into a rigid arm (Fig. 22c), which avoids the huge impact of the mooring line when suddenly straightened. With further improvement, the simple rigid arm evolved into a soft yoke arm (Fig. 22d) that connect the fixed tower and FPSO by means of hinges and a pendulum structure.

FPSO, Fig. 22 Development process of soft yoke

For the final yoke structure, the curve of soft yoke mooring forces to displacement has been completely smoothed to improve hydrodynamic performance of FPSO. In addition to the evolution of structure, the mooring force originally provided by buoyancy tank has changed into that provided by gravity of ballast tank (pendulum structure). Nevertheless, the restoring forces of buoyancy tank fluctuates constantly due to the tank motions under the excitation of waves, while the restoring forces provided by the gravity of the pendulum structure is more stable. Especially when the soft yoke system is completely off the wave surface, it will not be influenced by complex hydrodynamic loads.

Two Kinds of Yoke Mooring Systems

Two types of structures are now applied in yoke mooring systems, namely, the fixed-tower yoke mooring system and the single-column yoke mooring system, as shown in Fig. 23.

As a conventional yoke mooring system, the fixed-tower yoke mooring (Fig. 23a) consists of

several main structures: a truss tower fixed on seabed; a soft yoke that freely revolves around the tower and provides resilience on its own weight, including the A type soft arm structure itself (yoke) and the ballast load (or counterweight); the connection structure of the soft yoke and FPSO, such as the boom or chain; and the supporting structure on FPSO.

The single-column type yoke mooring system (Fig. 23b) also has similar components as mooring tower (column-type), rotational soft yoke, and connection and supporting structures. However, there is different design for the single-column type. Firstly, the yoke is hinged with the single column at the position on seabed, instead of over the free surface, thereby significantly reducing the overturning moment of the fixed structure. Secondly, yoke arms are connected to the main deck of the FPSO, thus avoiding the overhanging support structure above the deck height. This can effectively simplify the steel truss structure for mooring on the bow area. Thirdly, the risers are installed in the hollow single column to protect

FPSO, Fig. 23 Two kinds of yoke mooring systems.
(a) Yoke mooring system connected with fixed tower.
(b) Yoke mooring system connected with single column

F

them from wave slamming and ice crushing. The underwater yoke arms also avoid the harsh environmental loads on the surface area.

Shallow Water Effects on FPSOs with Yoke Mooring Systems

Because yoke mooring is more applicable for shallow water areas, thus much attention should be paid to effects of shallow water on FPSO hydrodynamics, which may make the hull collide the seabed and mooring system and then bring about damage.

Shallow water depth has obvious influence on the hydrodynamic characteristics of FPSO. With the decrease of ratio of water depth to draft, the natural periods of FPSO in heave, roll, and pitch modes increase accordingly. This means that when the wave period is larger and wave energy is concentrated in the low-frequency region in shallow waters, the probability of resonance, leading to strong motion responses of FPSO, will increase. Hence, the safety of yoke mooring system is threatened.

For the design of a FPSO soft yoke mooring system, the governing response is undoubtedly

the surge motion and load (Xiao et al. 2007). In shallow waters, especially the ultra-shallow waters, the surge motion and mooring force will be very large, and it will very seriously affect the single-point mooring system of a large FPSO.

With the decrease of the water depth in shallow water, it is found that the low-frequency response of surge motion and load increases enormously, while the high-frequency response keeps almost the same. It indicates that the low-frequency wave drift force on FPSO increases enormously in shallow water. This large amplitude increase of wave drift force may be caused not only by the change of natural period but also by the nonlinearity of the shallow water waves. Much more attention has been paid to the interaction mechanism between nonlinear shallow water waves and FPSO.

Trend on the Shipping Emission Control Regulations

With the gradual tightening of shipping emission reduction, the future trend on the

shipping emission prevention regulation is as follows.

The Scope of Emission Control Area (ECA) Will Be Further Expanded

The EU has been working for many years to expand the area applicable to the shipping emission control regulations through relevant amendments. Some other countries in the world have reached consensus and form synergy in advancing the establishment or expansion of emission control areas. In 2016, China established three sulfur emission control areas in the Yangtze River Delta, the Pearl River Delta, and the Circle-Bohai-Sea, respectively; see diagram in Fig. 1. From January 1, 2019, the sulfur emission control areas

was extended to the Yangtze River Mainstream, the Pearl River Mainstream, and all coastal waters.

Under the new Domestic Emission Control Area (DECA) regulation, oceangoing vessels that ply the inland river shall use 0.1% sulfur fuel beginning on January 1, 2020; the same applies to ships operating inside China’s Hainan waters from January 2022 onward.

In March 2019, South Korea’s National Assembly passed a Special Act on Air Quality Improvement in Port and Other Areas to combat air pollution from shipping and port activities. The Special Act stipulates a series of measures, the most conspicuous is to set up the ports air quality control zones, which are also called as South Korea ECA. On August 20, 2019, South Korea’s

F

Future Trend on the Design, Building, and Operation of Ships for Energy Efficiency, Fig. 1 Map of the domestic ECAs in China. (Picture from <http://www.huataimarine.com/index.php?m=newscon&id=361&twid=543>)

ECA regulation was released in a regulation advance notice, which covers Korea's five main seaports: Busan, Incheon, Yeosu-Gwangyang, Ulsan, and Pyeongtaek-Dangjin, and the regulation will be introduced in stages.

More Pollutant Items Will Be Introduced into the Emission Control Framework

From the initial control of sulfur content in fuel oil, to the control of NO_x in ship emissions, and to the control of the ship's energy efficiency design index (EEDI), more and more pollutant items have been introduced into the shipping emission control framework by IMO. In fact, in the EU *Technical Requirements for Inland Navigation Vessels*, there are more types of pollutants that are to be controlled, including NO_x, carbon monoxide (CO), hydrocarbon gas (HC), and PM, and limit values for pollution index are given to each type of pollutants. In *United States Code of Federal Regulations 40 CFR, Part 94*, the pollutants of NO_x, CO, HC, and PM are also controlled, and limit values for CO and PM pollution index are given, respectively, while for NO_x and HC, a comprehensive limit value is given by the combined pollution index of NO_x and HC. With the increase in the prevention and control of air pollution in ships and applications of new equipment (such as gas fuel engines) and alternative fuels (such as methanol) on ships, it is foreseeable that more and more types of pollutants will be controlled by the ship emission regulations in the future.

The Emission Standards Will Be Continuously Upgraded

Based on the implementation route, it can be seen that IMO's emission standards for SO_x and NO_x are phased and progressive. In the EU's *Technical Requirements for Inland Navigation Vessels* and US federal regulations, the engine emission standards for ships are also continuously upgraded. In China, the coastal waters of Hainan Province will implement 0.1% sulfur fuel oil requirements from 2022 in China. Besides, China will also assess the feasibility of using marine fuel oil with a sulfur content of not more than 0.1% in due course and determine whether it is required for marine vessels

entering the coastal control area to use marine fuel with a sulfur content of not more than 0.1%_{m/m} from January 1, 2025. With the advancement of technology, the improvement of social cognition level, and the increasing environmental protection from the government, the standards for air pollution emissions of ships will be gradually upgraded.

Trend on the Design, Building, and Operation of Ships for Energy Efficiency

Energy-Efficient Design for Ships

Conventional Energy-Saving Technology

For ships in service, the adoption of energy-saving technologies can improve ship energy efficiency and thereby reduce CO₂ emissions. These technologies include but are not limited to:

1. Optimization of propulsion mode, such as electric power propulsion or diesel-electric combined power propulsion
2. Optimization of propellers, such as using new types of propellers or counterrotating propellers
3. Optimization of inflow conditions of propellers, increase propulsion performance, and reduce fuel consumption by using additional devices (such as fins and/or nozzles)
4. Using energy-saving accessories, such as front tubes, flow deflectors, propeller boss cap fins (PBCF), etc.
5. Optimization of hull resistance, such as using anti-drag coatings
6. Optimization of rudder blades, improving rudder blade shape to reduce drag
7. Optimization of diesel engines and boilers, selecting low oil consumption and high-efficiency main and auxiliary engines and boilers
8. Installation of waste heat recovery system

Application of New Energy

By applying sails or kites during voyage, ships can use wind energy to reduce energy consumption and emissions of atmospheric pollutants.

Some fitted ships (such as vehicle carriers, cruise ships, etc.) have also tried to use solar energy. However, due to limitations of cost, utilization, and others, we are still facing a lot of challenges in the application of new energy sources such as wind and solar energy on ships.

Use of Alternative Fuels

Alternative fuels such as natural gas, biofuels, and fuel cell technology can significantly reduce greenhouse gas emissions from ships. Taking natural gas as an example, since its major composition is methane (CH_4), which has low carbon atom content and high hydrogen atom content. Therefore, under the same calorific value, CO_2 produced by the combustion of natural gas is lower than that of marine fuel. In terms of biofuel, the production is currently limited, and if the production is blindly increased, it may have a negative impact on the environment (such as deforestation, wetland reduction, etc.) and may also affect food prices. Fuel cells are environmentally friendly and have a good prospect for marine applications in the future. However, fuel cells are still in the process of trial or pilot and have a certain distance from large-scale practical applications. Overall, natural gas is the fastest-growing alternative fuel on ships, with the most mature technology and product support.

Energy Saving in Ships' Operation

Shore Power

Some types of ships require a large power supply during the port to maintain the operation of critical electrical equipment, such as cargo handling pumps on large tankers and essential equipment such as air conditioning, kitchen, and lighting on cruise ships. For these types of ships, the use of shore power can significantly reduce fuel consumption and CO_2 emissions during ship berthing.

Strengthen Ship Operation Management

Measures such as strengthening ship operation management and optimizing loading and unloading processes can reduce land transportation, alleviate port congestion, shorten ship waiting and

turnaround time, and reduce greenhouse gas emissions accordingly. These measures are both cost-effective and environmentally beneficial. These measures can achieve significant emission reduction effects in the short term and have good development prospects. However, improving the overall operational management level in the transport chain is far from being achieved by the shipowners or ship operators alone but, to some extent, depends on the coordinated actions of many stakeholders. Ship operations involve a wide range of stakeholders, including charterers, ports, and ship traffic management agencies. All parties should jointly consider introducing a coordination mechanism and carry out overall management of ship voyages, routes, cargo capacity, port utilization, etc., to minimize ships CO_2 emissions under the premise of ensuring ship traffic.

Slow Steaming

According to the empirical data of the ship's speed down navigation, the ship's speed is reduced by 4%, and the greenhouse gas emissions can be reduced by 13%. The gradual (mandatory or voluntary) reduction of ship's speed in specific areas (e.g., 200 nautical miles from the shoreline) can achieve the objective of maritime greenhouse gas emission reduction as early as possible. This measure can be effectively combined with measures such as ocean-meteorological navigation and voyage planning to ensure that the fuel consumption and air pollutant emissions for each voyage are minimized. However, the reduction in speed may cause problems in the ship operation. In order to win the market share, ships must have a competitive navigational speed. Since speed reduction will lead to an increase in the transmit time of the cargo and will result in more ships being used to transport the same amount of cargo. No matter applying other transport modes or more ships participating in the operation, more emissions will be generated.

Optimization of Ship Draft and Trim

The ship draft and trim have a certain impact on the ship's energy efficiency and carbon emissions. Ship draft will affect the ship's navigational

resistance. For a given draft, main power, and ballast conditions, the ship has an optimal trim attitude. By considering the hull, propeller pitch, main engine power, and other factors, the software can provide an optimal trim. At present, this software has been developed and put into use, and the CO₂ emission can be reduced by 1–2%.

Optimization of Propeller Energy Efficiency

By adjusting the immersed depth of propellers, the fuel consumption of the ship can be reduced. However, it should be achieved by adjusting ballast, loading, fuel oil, fresh water tanks, and the main engine speed. By checking the surface condition of propellers, maintaining the surface finish of the blade, and repairing the damaged blade (crimping, corrosion) in time, the efficiency of propellers can be improved and the energy consumption of ships can be reduced.

Well Hull Maintenance

The growth of marine organism on the surface of hull will increase the ship's resistance, while regular hull cleaning can reduce ship's resistance and fuel consumption. In order to increase the energy efficiency, some measures can be undertaken on the hull, which include coatings to ensure the smoothness of the hull to reduce the attachment of marine organism and reduce the resistance of the hull; regular hull maintenance, in case ship fouling is accumulated and affects the speed of the ship; regular inspection and cleaning of the hull condition, ensuring that the ship is regularly docked and assessing the performance of the ship; and timely removal and replacement of underwater paint to avoid increasing the hull roughness which is caused by repeated blasting or multiple docking repairs.

Definition

Underwater Glider (UG) is a new type of autonomous underwater vehicle (AUV), which can

perform three-dimensional observation from the surface to its working depth. UG follows a typical sawtooth-like profile in the ocean. The observation duration is generally several months, and the cruising range capacity can reach thousands of kilometers. It has the characteristics of low noise, low cost, and round-the-clock service. It can carry different mission sensors (e.g., CTD, Shear Probe) and is equipped with GPS navigation and positioning system. It has become a quasi-real-time, sustainable, large-scale, and high-resolution platform for marine observation and detection.

The concept of UG, a glider with a buoyancy engine powered by a heat exchanger, was first introduced to the oceanographic community by Henry Stommel in 1989, when he proposed a glider concept called Slocum, developed with research engineer Doug Webb from Woods Hole Oceanographic Institution (WHOI), founded by Naval Technology (ONR) (Stommel 1989). Today, the mature UG products on the market mainly include: the battery-powered SLOCUM glider of United States Teledyne Webb Research (TWR) (Webb et al. 2001), the Seaglider of United States Bluefin Robotics (Eriksen et al. 2001), the Spray glider of United States iRobot (Sherman et al. 2001), the Petrel glider of Tianjin University (TJU) (Ma et al. 2018; Liu et al. 2014a), and the Sea-Wing of Shenyang Institute of Automation at Chinese Academy of Sciences (SIA) (Yu et al. 2017).

Scientific Fundamentals

Glider Types

Based on the characteristics of different driving modes, there are few types of UG products: buoyancy-driven UG, hybrid underwater glider (HUG), and environmental-energy-driven UG. Jo Borchsenius proposed to use marine chemical energy to drive UG (Borchsenius and Pinder 2010); M. Arima developed a solar-energy-driven prototype UG (Arima et al. 2011); Andrea Caiti conducted a theoretical study of wave-energy-driven UG (Caiti et al. 2011); Webb Research Cooperation developed a thermal-driven UG (Webb et al. 2001).

Historical Development

Nowadays, the UG technology is mainly developed by the USA, France, Britain, and Australia. As the initiator and leader of the UG technology, the USA has been dedicating to study UGs since the 1990s. Today, the US UG technology has been mature with plenty of types of UGs such as Slocum, Spray, Seaglider, and ANT glider (Кожемякин et al. 2016).

In January 1991, TWR's first Slocum glider was marked as the birth of UG (Schofield et al. 2010).

In 1999, American institutions Scripps Institution of Oceanography (SIO) and WHOI worked together to develop the Spray glider. This glider's working depth was 1500 m (Rudnick et al. 2016). Then, the Spray glider was commercialized by the Bluefin Robotics Corporation.

In 1999, Applied Physics Laboratory at the University of Washington (APL, UW in America) developed the Seaglider. They designed a pressure hull whose compressibility was close to the sea water's, which could decrease the buoyancy change amount and save energy (Rudnick et al. 2004). Today, the Seaglider has been commercialized by Kongsberg Maritime.

In recent years, with the funding from the Office of Naval Research (ONR), an American company, the Exocetus Development LLC, developed the Exocetus Coastal glider (formerly called the ANT Littoral glider), which is applied in the

shallow seas. Till now, it has delivered 18 UGs to the US Navy, which has been operated for 4500 h.

With the extensive application of UG and the increase in their usage demand, the hybrid UG has gradually become the research hotspot in recent 10 years in order to improve underwater glider's antirflow capability in strong ocean currents.

In 2004, R. Bachmayer et al. from Princeton University in America proposed the concept of HUG's design for the first time. The underwater glider is equipped with a propeller on the tail to realize hybrid propulsion (Bachmayer et al. 2004).

In 2008, the French company ACSA developed the HUG SeaExplorer. It is integrated with the propeller system, which can switch modes freely between AUV/glider modes. Combined with an underwater acoustic positioning system, it can realize positioning without coming to the surface. It can be used for long-term and under-ice measurement. Now, SeaExplorer has been commercialized (Claustre et al. 2014).

In 2009, NATO Undersea Research Centre (NURC) began to develop the hybrid UG Folaga (Alvarez et al. 2009). In the same year, the French institution ENSIETA developed the hybrid UG Sterne (Wood and Mierzwa 2013).

In 2011, Monterey Bay Aquarium Research Institute (MBARI) developed a hybrid UG Tethys AUV. The glider's tail is equipped with a propeller which can realize short-term hybrid propulsion.

National Research Council Canada (NRC), the Memorial University of Newfoundland (MUN), and TWR added folding propeller thrusters to the tail of a Slocum glider made by TWR in 2012 to enhance the current glider's mobility in the shallow sea and expand the glider's scope of applications. When propulsion is needed, the propeller of the glider is deployed to increase the speed. When gliding is required, the glider's propeller folds to reduce the gliding resistance.

The UG research in China started in the early twenty-first century. In 2005, TJU developed a prototype of a UG driven by temperature difference energy. SIA developed a prototype of the UG prototype (Wang et al. 2005, 2006).

Since 2007, with the support of China National 863 Program, TJU developed a prototype of the

hybrid UG, while SIA carried out the research and development of the UG prototype in 2008. Zhejiang University (Yang et al. 2014), National Ocean Technology Center of China (Qin et al. 2016), Yichang Research Institute of Testing Technology at China Shipbuilding Industry Corporation (Chen et al. 2014), Shanghai Jiao Tong University, and Northwestern Polytechnical University (Tian et al. 2013) also conducted relevant studies on gliders. In recent years, China Ship Scientific Research Center of China Shipbuilding Industry Corporation has also researched UGs deeper than 500 m (Ma et al. 2007).

In 2012, TJU, SIA, Huazhong University of Science and Technology, and Ocean University of China jointly undertook a National 863 Program's project. This project had developed many types of UG engineering prototypes, which accelerates the deep-sea UG technology engineering.

From March to April 2014, relying on the above project, many types of UGs participated in the sea trial research in the South China Sea, which shortened the technical gap between China and other countries as well as established a foundation for the future productization of the UG.

From April to June 2015, TJU deployed several Petrel-II UGs to participate in the sea trials organized by Ministry of Science and Technology of China, which achieved fault-free work for 30 days and set several Chinese records such as 229 deep-sea observation profiles of 1000 m deep and 1022.5 km cruising range.

In March 2017, the Sea-Wing 7000 UG developed by SIA completed the deep-sea observation mission in the Mariana Trench, reaching a maximum depth of 6329 m.

In April 2018, the Petrel-X UG developed by TJU made its dive to 8213 m in the Mariana Trench, setting a world record for the working depth of the deep-sea gliders.

In May 2018, the long-voyage UG Petrel-L (Fig. 1), developed by TJU, operated for 119 consecutive days, completed 862 profiles, and completed the range of 2272.4 km. Again it has set some new records of Chinese UGs, including the longest continuous working time, the most measured profile, and the longest endurance distance, etc.

In recent years, China has also made key technological breakthroughs in hybrid UGs. Today, the Petrel HUG of TJU has completed the product design finalization and is being actively promoted and demonstrated.

The specific performance indexes of the mentioned commercial and developing UGs are summarized in Table 1.

The Key Technology in the Development of a Glider

UG's technical direction can be grouped into single-machine technology and networking technology (Fig. 2). Single-machine technology includes buoyancy-driven technology, multimode hybrid propulsion technology, attitude adjustment technology, lightweight pressure-resistant hull technology, and small low-power sensor design

Glider, Fig. 1 Petrel-L glider

Glider, Table 1 UGs and their specifications

Name	Development organization	Specifications
Slocum electrical glider 	TWR, USA	Slocum G2: 1.5 m long, 0.22 m in diameter, the net weight of 55–70 kg, horizontal speed of 0.35 m/s Depth options of 30 m, 100 m, 200 m, 350 m and 1000 m (modular buoyancy engine dependent) Range: 350–1200 km (Alkaline batteries), 700–3000 km (Rechargeable batteries), and 3000–13,000 km (Lithium batteries) Deployment Length: 15–50 days (Alkaline batteries), 1–4 months (Rechargeable batteries) and 4–18 months (Lithium batteries)
Spray glider 	SIO and WHOI, USA	2 m long, 1.2 m wide, 51 kg net weight, deployment length of 6 months, operation speed of 0.23 m/s (max 0.25 m/s), range of 3600 km, and maximum depth of 1500 m
Seaglider 	APL, UW, USA	1.8 m long, 0.3 m in diameter, 1 m wide, antenna mast length of 1 m, 52 kg, depth of 1000 m, the range of 4600 km, 24 V, and 10 V batteries, 10 MJ, typical speed of 0.25 m/s
ANT Littoral glider/Exocetus coastal glider 	Exocetus Development LLC, USA	2 m long, 0.32 m in diameter, 2 m wide, 120 kg, depth of 200 m, maximum volume changeability of 5 L, the speed of 1 m/s
SeaExplorer hybrid glider 	ACSA, France	2 m long, 0.25 m in diameter, antenna mast length of 0.7 m, 0.565 m wide, 59 kg, maximum volume changeability of 1 L, the maximum horizontal speed of 0.5 m/s, the payload of 8 kg, depth of 700 m, deployment length of 2 months
Folaga hybrid glider 	NURC	2 m long, 0.14 m in diameter, 30 kg, the maximum horizontal speed of 1 m/s, the payload of 8 kg, depth of 100 m

(continued)

Glider, Table 1 (continued)

Name	Development organization	Specifications
Sterne hybrid glider 	ENSIETA Institution, France	4.5 m long, 0.6 m in diameter, 990 kg
Tethys hybrid glider 	MBARI, USA	2.29 long, 0.305 m in diameter
Slocum hybrid glider 	MUN, NRC and TWR, USA	Add folding propeller thrusters to the tail of a Slocum glider
Petrel-II hybrid glider 	TJU, China	1.8 m long, 0.3 m in diameter, 70 kg, depth of 1500 m, the speed of 0.5 m/s, design cruising range of 1500 km, deployment length of more than 40 days
Sea-Wing glider 	SIA, China	2.5 m long, 0.22 m in diameter, 1.2 m wingspan, 65 kg, depth of 1000 m, cruising range of 1000 km, the speed of 0.5 m/s, deployment length of more than 30 days
Other gliders of China 	Huazhong University of Science and Technology, Yichang Research Institute of Testing Technology at China Shipbuilding Industry Corporation, and Ocean University of China, etc., China	All tested in the South China Sea

Glider, Fig. 2 UG's main technical direction

technology; networking technology is oriented to high reliability and practical UG as well as conducting synergistic formation networking technology research.

Buoyancy-Driven Technology

Buoyancy-driven system is a set of a mechanical, electrical, and hydraulic coupling system with the function of volume change. It directly determines UG's performance and reliability which also affects the speed, range, and maneuverability of UG. Buoyancy-driven systems can be divided into two categories according to the method of volume change: One is to transport hydraulic oil between an internal and external bladder by pumps or pistons, such as the Seaglider and Spray gliders using reciprocating piston pump and Slocum electric gliders using single stroke pistons. The other is thermal engine through thermal expansions and contractions of PCM. Thermal engines can directly obtain the required energy from the environment for buoyancy change it

limited by the range of thermocline in different ocean areas. Table 2 shows the comparison of main technical parameters of the buoyancy-driven system of commercial UG, such as Slocum, Seaglider, Spray, and SeaExplorer (France), with Petrel developed by TJU (Davis et al. 2002; ALSEAMAR 2018).

In order to meet the needs of deep-sea observation technology, Deepglider of USA (Osse and Eriksen 2007), UnderDOG UG of New Zealand and high-pressure buoyancy-driven system with a depth of 2100 m of Japan all use the high-pressure buoyancy-driven system with micro axial piston pump as the core (Townsend and Shenoi 2016; Asakawa et al. 2016; Ma et al. 2016).

Multimode Hybrid Propulsion Technology

Multimode HUG has many advantages, such as better maneuverability, lower power consumption, longer cruising range, and stronger stealth. Multimode HUG is mainly driven by buoyancy, supplemented by propeller propulsion or water jet

Glider, Table 2 Technical parameters of typical UG's buoyancy driven system

UG	Institute	Technical parameters
Slocum	TWR, USA	Working depth: 200 m/1000 m Capability: 0.46 L 200 m, 0.52 L 1000 m Drive type: piston driven by lead screw/piston pump System efficiency: 50~60% (lead screw)
Seaglider	APL UW, USA	Working depth: 1000 m Capability: 0.85 L Drive type: piston pump System efficiency: 40%
Spray	Scripps UC, USA	The depth of design: 1500 m Working depth: 1000 m Capability: 0.7 L Drive type: piston pump System efficiency: 40%
ANT Littoral glider/Exocetus coastal glider	ANT, USA	Depth of design: 200 m/1000 m Drive type: pump/variable section piston
SeaExplorer	ACSA, France	Working depth: 850 m/700 m Capability: 1 L Drive type: pump System efficiency: 60%
Petrel	TJU, China	Working depth: 1500 m Capability: 1.4 L Drive type: piston pump System efficiency: 34%@1000 m, 40%@1500 m

propulsion. It realizes the functions of dynamic gliding and horizontal propulsion, improves the speed and manoeuvrability of UG to a certain extent, and enriches the movement mode of UG. However, the realization of these functions will inevitably increase its energy consumption and reduce its endurance. For this kind of technical difficulty, TJU has carried on a system analysis to the HUG movement pattern and the stability (Niu et al. 2017; Yang et al. 2016; Lei et al. 2016). Also, TJU has designed and developed a winged HUG, “Petrel” (Qin et al. 2017; Wang et al. 2011; Liu et al. 2014b). Harbin Engineering University has designed an underwater vehicle with a plastic shell and a water jet propeller (Guo et al. 2010, 2011).

Attitude Adjustment Technology

UG is a multibody system composed of shell, attitude adjustment system, and buoyancy adjustment system. The attitude adjustment system is an important part of UG, which is generally divided into “only the internal attitude adjustment technology” and “tail rudder and internal attitude

adjustment technology.” The internal attitude adjustment system achieves the adjustment of UG's barycenter position by controlling the movement of the mass block in the cabin to achieve effective attitude control.

1. Only the internal attitude adjustment technology

Only the internal attitude adjustment system is composed of a pitch adjustment mechanism and roll adjustment mechanism. According to the set gliding angle, the pitch adjusting mechanism controls the mass block to move along the UG axis to achieve UG's ups and downs. Moreover, the roll adjusting mechanism regulates the turning of UG by controlling the circumferential rotation of the eccentric mass block. The internal attitude control method, which controls the axial translation and circumferential rotation of the mass blocks in the cabin, applies to deep sea UG, such as Spray, Slocum thermal, Seaglider, Deepglider, and so on. These gliders all adopt dc motor to drive eccentric mass block for attitude

adjustments, which are usually the battery pack in the cabin. The attitude control of Petrel-II UG developed by TJU in China also adopts this method (Sang 2018).

2. Tail rudder and internal attitude adjustment technology

The UG structure that adjusts the attitude by adopting the axial translation of the mass cabin block and using the tail rudder attached to the UG's tail is relatively simple and is suitable for performing tasks in shallow water with relatively complex topography and geomorphology. For example, the battery-powered Slocum UG uses a stepper motor to adjust the steering of the tail rudder, which dedicates to control the steering of the UG. Similar to the battery-powered Slocum UG, the Sea-Wing UG developed by SIA, also adjust its attitude of UG by adjusting the tail rudder through stepper motor.

Lightweight Pressure-Resistant Hull Technology

When UG runs in the ocean, the seawater pressure it receives is proportional to the depth of the dive. Under external pressure, if the hull is deformed, buoyancy changes and even failure of the pressure-resistant hull may be caused. Therefore, it is especially important to optimize the structure of the UG pressure-resistant hull (Liu et al. 2013). To meet the demand for pressure requirements as well as having relatively lightweight, Wang et al. (2008) analyzed the structural parameters of the UG pressure-resistant hull. Based on the optimization of the UG's main body shape and improvement of the shell material, Song et al. (2014) used finite element analysis to analyze the structure and size of the UG's pressure shell. He et al. (2018) carried out a multiobjective optimization on the parameterized model of multibubble pressure chamber structure, using Kriging interpolation method and nondominated sorting genetic algorithm.

Small Low-Power Sensor Design Technology

At present, the design of small-scale and low-power sensors applied in gliders abroad has developed rapidly. The integration of multisensor and gliders has been successfully developed and implemented, and the substantial progress has

been made remarkably. In the design and integration of marine sensors, China possesses a good development basis, but the small-scale and low-power sensors for UG application have a large gap existing, compared to the international advanced technology level.

Synergistic Formation Networking Technology

UG can realize continuous observation and detection in long range and large scale in the complex ocean environment, and the formation, networking, and coordinated observation are the most important application modes of the UG. In almost all of the important international ocean observation systems and programs, there are research missions and application experiments for UG formation and network construction, showing the important role of UG network in ocean monitoring and detection. The comprehensive research of multi-UG formation network technology in China is still in its infancy stage. Moreover, key technologies involved in this section include multi-UG formation and collaborative control and network construction technologies.

Key Applications

Today, the UG platform is widely used worldwide, showing important application value in many aspects. It can greatly meet the various needs of marine science, marine economic development, disaster prevention, and national defense technology.

Civilian Demands

Emergency Response

UG can be used for emergency response, such as monitoring marine pollution, marine search and rescue. In the disaster of the oil spill in the US Gulf of Mexico on April 20, 2010, many organizations, enterprises, and research institutes volunteered to deploy multiple UGs to observe the temperature, salinity, and current velocity of the sea area to confirm the further moving direction of the crude oil.

Climate Variability Observation

A wide range of climate variability has emerged with the occurrence of the El Niño phenomenon. Today, the key observation to study climate variability is the boundary flows. Moreover, UG can provide strong support for climate variability study. Compared to other observation systems, UG can sample the dynamic environment continuously, which makes it an ideal platform for boundary flow observation. As early as 2004, UG had observed a boundary flow from Woods Hole and crossed to the Bermuda Islands. In 2009, the famous Scarlet Knight Slocum UG succeeded crossing to Atlantic, which had demonstrated that the UG has reliable sailing performance and long-lasting operational capability.

Marine Disaster Forecast

1. UG has reliable sampling capability in extreme environments, which can observe real time when the hurricane/typhoon passing and feed-back important first-hand dynamic temperature and salinity information; thus, the UGs can greatly improve the accuracy of hurricane/typhoon wind forecast, and make an important contribution to the safety of human life and property.
2. UG has the capability of multidimensional observation for Harmful Algal Blooms (HABs). Currently, a multidisciplinary crossed observation system with multiple platforms, which is constituted of the UG networks, satellites, surface ships, and mooring equipment, has become a new observation method for phenomena such as HABs.
3. Low dissolved oxygen is a big environmental issue, which affects marine water quality and fishery. UG has been successfully applied to complete the sampling task of dissolved oxygen in the offshore waters of the USA, Australia, and China.

Military Demands

The US military has developed advanced underwater winged gliders based on UG's acoustic application, acoustic UG XRay, and ZRay. They can be used for submarine monitoring and various low-frequency sound source monitoring (Stephen

2009; D'Spain et al. 2005). Therefore, UG platform has great utilization potentiality in national marine defense security field.

XRay

The XRay was developed primarily with the aid of the Marine Physical Laboratory, SIO and the APL, UW in 2005. It is designed to achieve the cruise speed of 1–3 knot and can realize the gliding range of 1200–1500 km, and be able to remain on-station up to 6 months in partial buoyant glides (Arima et al. 2014) (Fig. 3).

The vehicle is the largest UG with 6.1 m wingspan, which has an advantage regarding hydrodynamic efficiency and space for energy storage and payload. The lift to drag ratio was 17/1 in the sea trial in 2005. XRay's payload includes a low-power 32-unit hydrophone array placed along the leading edge of the wing, a large physical aperture for medium frequency (1–10 kHz) and a 4-component vector sensor. The cumulative data collected by the array illustrates the performance of the narrowband detection and localization algorithm. The flying behavior development of the flying wing maximizes the detection and positioning capabilities of the array. XRay 2 was improved in 2007 and had conducted 55 field tests in 2008, which verified that its specific flying behavior could improve the detection and positioning of hydrophone arrays.

ZRay

ZRay is an autonomous underwater vehicle funded by the ONR and developed by a team funded by the ONR and developed by a team funded by the SIO, the APL, UW, and the US Navy's Space and Naval Warfare Systems Center Pacific. The 6 m wide blended wing-body hull form glider was completed in 2010 and is based on the Liberdade class model developed by ONR since 2004 (Hildebrand et al. 2009).

ZRay collects acoustic data via a 27-element hydrophone array installed in sonar housing in the glider's leading edge. Wide-band acoustic sensors are also located in the nose and tail. The long endurance (1 month, 1000 km range) vehicle has oceanographic and potential antisubmarine warfare applications. In 2011, ZRay conducted

Glider, Fig. 3 XRay glider in SIO (Office of Naval Research 2006)

Glider, Fig. 4 ZRay glider (D'Spain 2012)

testing off San Diego in support of the Navy's Passive Acoustic Autonomous Monitoring (PAAM) of Marine Mammals Program. PAAM is designed to track marine mammals over long periods in Navy acoustic testing areas (Fig. 4).

LBS-G

Teledyne Brown Engineering, Inc., built the Littoral Battlespace Sensing-Glider (LBS-G) for the US Navy to obtain important oceanographic data and improve the fleet positioning during naval exercises. Considering the influence of the temperature layer on sonar propagation, the LBS-G

has obvious functions for hidden and submarine hunting.

The LBS-G is propelled by changes in buoyancy along with its wings and tail-fin steering. The LBS-G can operate up to 30 days per time by a Lithium battery. Its dive depth is less than 1000 m, and the single section can glide 5,000 m. The sensors in the “nose” collect oceanographic data. While on the surface, LBS-G reports its location, transmits data via satellite, and receives mission orders.

In 2009, the LBS-G glider completed the transatlantic mission in 223 days. Pilot production

Glider, Fig. 5 Engineers run predeployment inspections on a littoral battlespace sensing glider. (US Navy photo by Rick Naystatt)

began at the end of 2010. In 2011, it was approved by the US Navy to enter the mass production phase of the underwater coastal theater LBS-G project. In 2013, the US Navy increased the investment in this project, hoping to apply it as “the important landmine countermeasures and other missions for expeditionary warfare, which intends to reduce or eliminate the times of sailors and marines enter into dangerous shallow and offshore regions to clear landmines” (U.S. Navy Program Guide 2012 2014) (Fig. 5).

Global Buckling of Offshore Pipelines

Run Liu and Chengfeng Li
State Key Laboratory of Hydraulic Engineering
Simulation and Safety, Tianjin University,
Tianjin, China

Introduction

Pipelines constitute a vital means of transporting and distributing liquids and gases such as oil, gas, and water over long distance. Since the early 1970s of the last century, pipelines have become one of the main means of transporting offshore oil and gas in many parts of the world. In-service hydrocarbons must be transported at high pressure/high temperature (HP/HT) to ease the flow and prevent solidification of the wax fraction. The difference between the high-pressure/high-temperature (HP/HT) and the as-laid conditions would cause pipelines to expand. The axial

expansion, however, is restrained either by soil friction, rocks, or anchors, thus inducing significant compressive axial loads in the pipeline wall. When the axial force reaches the lowest global buckling capacity, the pipeline will buckle globally, and the effective axial force will drop. If the pressure or temperature is further increased, the post-buckling will happen.

Global buckling of a pipeline means the loss of stability of the pipeline similar as a bar in compression. The global buckling may appear either horizontally (lateral buckling on the seabed) or vertically (upheaval buckling of buried pipelines) (DNVGL-RP-F110 2017). As shown in Fig. 1, both the upheaval and lateral buckling of pipelines can have serious consequence for the integrity of a pipeline. Consequently, considerable studies have focused on the global buckling of pipelines and intend to provide reasonable design guidance to prevent or control global buckling of pipelines.

There is a large volume of material published on both the upheaval and lateral buckling of pipelines, which covered the different related aspects of the buckling pipelines including mechanism of global buckling, parameter analysis, engineering case study, and mitigation measures for global buckling. The buckling mechanism of a pipeline is the basis of other related researches. This entry aims to describe the history of the theoretical studies on the global buckling of offshore pipelines (i.e., vertical buckling of buried subsea pipeline and lateral buckling of pipelines exposed on seabed). This entry also provides summarized information of the current state of the art and achievement in this area by summarizing published literature including also possible review

Global Buckling of Offshore Pipelines, Fig. 1 Upheaval and lateral buckling of pipelines (Bruton et al. 2007)

articles. Engineers are hoped to benefit from the extensive literature review.

Theoretical Background: Global Buckling and Its Mechanism

Global buckling of an offshore pipeline operated at HP/HT can be described as Fig. 2. When the temperature or pressure increases, the effective axial compressive force will be induced in the pipeline. If the pipeline is fully restrained, the compressive axial force will increase to the maximum effective axial force that can occur in a pipeline (i.e., the fully constrained force in Fig. 2).

For a pipeline with free ends, the axial force will be released as the pipeline experiences greater end expansion, so the force at the ends is zero. However, as the cumulative axial resistance increases with distance from the pipeline ends, the force can increase to a condition of full constraint over some of its length, as illustrated by the black line in Fig. 2.

According to Hobbs (1984), this could lead to global buckling of the pipeline if the compressive axial force reaches the critical buckling force. The force in the buckle drops as the buckle develops, which will cause the pipeline section around the buckle to axially feed in to the buckle. The feed-in results in the axial force release in the slip zone. As illustrated by the blue line in Fig. 2, the slope of the force profile in slip zones is governed by the axial friction, and the length of the slip zone depends on the available frictional resistance to oppose the feed-in. And a virtual anchor will be developed at the end of the feed-in zone.

Figure 2 shows the scenario for the post effective force of pipeline within a single isolated buckle. For a pipeline with a longer length, it is possible that more than one buckle forms in the system (Carr et al. 2003), as illustrated in Fig. 3, where the pipeline has formed three buckles (the number of buckles is entirely case dependent).

Between adjacent buckles there must be a virtual anchor point at which the direction of pipeline

Global Buckling of Offshore Pipelines, Fig. 2 Post effective force of pipeline within a single isolated buckle. (Adapted from Carr et al. 2003)

Global Buckling of Offshore Pipelines, Fig. 3 Post effective force of pipeline within more than one buckle. (Adapted from Carr et al. 2003)

expansion changes. This effectively divides the pipeline up into three short pipelines anchored at each end and a discrete series of isolated buckles between anchor points. According to the paper (Bruton et al. 2007), as the buckles are spaced such that the distance between successive buckles is less than the total buckle length of a long pipeline ($L + 2L_s$ in Fig. 4) of an isolated buckle, the feed-in is shared between the two buckles that is known as expansion sharing in DNV (DNVGL-RP-F110 2017).

Global Buckling of Pipeline on Rigid Foundation

The rigid-base model is an approach that uses a beam on a rigid base with Coulomb friction to analyze the problem of in-service buckling of pipelines, both upheaval and lateral. In this model the pipeline-soil interaction is constant and determined by the buoyancy density and friction coefficient, independent of the deflection of the pipeline.

Hobbs' Model for Perfect Straight Pipelines

Vertical buckling model. Based on the rigid-base model of a straight railway track described by Kerr (1974), Hobbs (1981, 1984) has described a rigid-base model for a long pipeline within vertical buckling (ref. to Fig. 4).

A linear differential equation has been established to describe the imperfection shape of the buckled part of the pipeline. It is assumed that the bending moment at the liftoff point is zero. In the notation of Fig. 4,

$$y'' + n^2 y + \frac{m}{8} (4x^2 - L^2) = 0 \quad (1)$$

where $m = w/EI$, $n^2 = P/EL$, and w is submerged weight of pipeline (including weight coat) per unit length.

With the boundary conditions $y|_{x=0} = v_m$, $y_x|_{x=0} = 0$ and $y|_{L/2} = y_x|_{L/2} = y_{xx}|_{L/2} = 0$, the following results are obtained by

$$P = 80.76 \frac{EI}{L^2} \quad (2)$$

Global Buckling of Offshore Pipelines, Fig. 4 Axial force of a pipeline with vertical buckling. (Adapted from Hobbs 1981)

$$P_0 = P + \frac{wL}{EI} \left[1.597 \times 10^{-5} EA \phi w L^5 - 0.25 (\phi EI)^2 \right]^{\frac{1}{2}} \quad (3)$$

where P is the axial load in the buckle and P_0 is the axial load away from the buckle (Fig. 4). P_0 created by full restraint of thermal expansion is simply $P_0 = AE\alpha T$. ϕ is the coefficient of friction between pipeline and subgrade.

The maximum amplitude of the buckle is

$$v_m = 2.408 \times 10^{-5} \frac{wL^4}{EI} \quad (4)$$

And the maximum bending moment, at $x = 0$, is

$$M_m = 0.06938 w L^2 \quad (5)$$

Lateral buckling model. With the vertical analysis to hand, the lateral buckling had been analyzed for the case of mode 1–mode 4 and mode ∞ (Fig. 5) by Hobbs (1984).

The values obtained for compressive loads and buckle amplitude are of the same form as Eqs. (2–5), but with different constant k_1 – k_5 . The appropriate constants can be found from Table 1:

$$P = k_1 \frac{EI}{L^2} \quad (6)$$

$$P_0 = P + k_3 \phi w L \left[\left(1.0 + k_2 \frac{AE \phi w L^5}{(EI)^2} \right)^{0.5} - 1 \right] \quad (7)$$

$$v_m = k_4 \frac{\phi w}{EI} L^4 \quad (8)$$

$$M_m = k_5 \phi w L^2 \quad (9)$$

Taylor's Model for Imperfect Pipelines

Engineering practice shows that the in situ shape of a pipeline in practical terms is far from being straight. The imperfections concerned may include a crest in the seabed profile, or a prop, as when isolated rock is located immediately below the line or another pipeline is to be crossed. Figure 6 describes three types of imperfection adapted from Taylor and Tran (1993). With the temperature rising, buckling may take place in the pipeline because of the existence of initial imperfection. Many researches have been performed on imperfect pipelines.

Global Buckling of Offshore Pipelines, Fig. 5 Lateral buckling modes of Hobbs' analytical solution (Hobbs 1984)

Global Buckling of Offshore Pipelines, Table 1 Constants for lateral buckling modes (Hobbs 1984)

Mode	k_1	k_2	k_3	k_4	k_5
1	80.76	6.391×10^{-5}	0.5	2.407×10^{-3}	0.06938
2	$4\pi^2$	1.743×10^{-4}	1.0	5.532×10^{-3}	0.1088
3	34.06	1.668×10^{-4}	1.294	1.032×10^{-2}	0.1434
4	28.20	2.144×10^{-4}	1.608	1.047×10^{-2}	0.1483
∞	$4\pi^2$	4.7050×10^{-5}		4.4495×10^{-3}	0.05066

Taylor and Gan (1986) proposed a modified version of the Hobbs' model, in which the pipeline has an initial imperfection of amplitude v_o and length L_o . In their analysis, the morphological expression of the initial geometric imperfection of the pipeline was similar to the buckling deformation of perfect straight pipelines given by Hobbs. And they considered that the buckling of pipeline was the growth of initial imperfections. The essential features of the vertical mode are shown in Fig. 7. The submerged self-weight of the pipeline per unit length is denoted by q , and v_m represents the maximum amplitude of the buckled pipeline.

Based on the buckling amplitude of perfect straight pipelines, the imperfection deflection expression can be assumed to be

$$v_o = \frac{v_{om}}{k_1} \left(1 + \frac{n_o^2 L_o^2}{8} - \frac{n_o^2 x^2}{2} - \frac{\cos n_o x}{\cos n_o L_o / 2} \right) \quad (10)$$

$$-L_o/2 \leq x \leq L_o/2$$

$$v_m = 2.407 \times 10^{-3} \frac{q}{EI} L_o^4 \quad (11)$$

Employing symmetry, the total potential energy relating to the deformed state is given by

$$V = \int_0^{L_o/2} EI/2 (d^2v/dx^2 - d^2v_o/dx^2)^2 dx + \int_{L_o/2}^{L/2} EI/2 (d^2v/dx^2 - d^2v_o/dx^2)^2 dx + \int_0^{L_o/2} q(v - v_o) dx + \int_{L_o/2}^{L/2} q(v - v_o) dx - \int_0^{L_o/2} P/2 [(dv/dx)^2 - (dv_o/dx)^2] dx - \int_{L_o/2}^{L/2} P/2 [(dv/dx)^2 - (dv_o/dx)^2] dx = 0 \quad (12)$$

The corresponding equilibrium state being given by $dV/dv_m = 0$. Substitute Formula (10)

Global Buckling of Offshore Pipelines,

Fig. 6 Typical imperfection configurations (Taylor and Tran 1993)

Global Buckling of Offshore Pipelines, Fig. 7 Vertical buckling of mode 1 triggered by a single-arch symmetric imperfection (Taylor and Gan 1986)

and Formula (11) into Formula (12) to obtain the expression of P :

$$P = 80.76 \frac{EI}{L^2} \left[1 - \frac{R_1}{75.60} \left(\frac{L_o}{L} \right)^2 \right] \quad (13)$$

where

$$R_1 = 4.60314 \left[\sin(4.4934L_o/L) + 2.30157 \left(\frac{\sin 4.4934(1 + L_o/L)}{(L/L_o + 1)} + \frac{\sin 4.4934(1 - L_o/L)}{(L/L_o - 1)} \right) \right]$$

For pipelines with imperfection ratios V_{om}/L_o varied from 0.003 to 0.010 and the remaining pipeline parameters fixed, the relationship between the buckling force and buckling amplitude can be produced by substituting the parameters into the above formula, as shown in Fig. 8. It shows that the smaller the imperfection amplitude is, the greater the buckling force is. For the relatively small imperfection ratio case (0.003), it displays a maximum buckling force P_m , in which the snap buckling phenomenon can be clearly observed. The remaining two cases (0.007 and 0.010) generate stable post-buckling paths.

Based on the analysis of vertical buckling, Taylor also studied the lateral buckling of the first mode and the second mode. The analysis for the buckling region is identical to that of the vertical mode. For the lateral buckling of the first mode,

the values obtained for compressive loads and buckle amplitude are of the same form as Eq. (13). For the lateral buckling of the second mode, the topology and axial force distribution can be depicted as Fig. 9.

Antisymmetric imperfection expression (Taylor and Gan 1986):

$$v_o = \frac{v_{om}}{k_2} \left[1 - \cos\left(\frac{2\pi x}{L_o}\right) + \pi \sin\left(\frac{2\pi x}{L_o}\right) + \frac{2\pi^2 x}{L_o} \left(1 - \frac{x}{L_o}\right) \right] \quad 0 \leq x \leq L_o \quad (14)$$

where

$$v_m = 5.532 \times 10^{-3} \frac{\phi_L q L_o^4}{EI}$$

Substitute Formula (14) into Formula (12) to obtain the expression of P (Formula 15) by applying the statics criterion $dV/dv_m = 0$:

$$P = \frac{4\pi^2 EI}{L^2} \left[1 - \frac{3}{5} \left(\frac{R_2}{3\pi + \pi^3} \right) \left(\frac{L_o}{L} \right)^2 \right] \quad (15)$$

Global Buckling of Offshore Pipelines, Fig. 8 Thermal action characteristics – vertical mode (Taylor and Gan 1986)

Global Buckling of Offshore Pipelines,

Fig. 9 Lateral buckling of mode 2 triggered by a two-arch antisymmetric imperfection (Taylor and Gan 1986)

Global Buckling of Offshore Pipelines, Fig. 10 Global buckling of mode 3 triggered by a single-arch symmetric imperfection (Hong et al. 2015)

where

$$R_2 = \sin(2\pi L_o/L) \left[\frac{(L/L_o)(\pi^2 + L/L_o)}{1 - (L/L_o)^2} \right] + 2\pi L_o/L$$

$$+ \pi [1 - \cos(2\pi L_o/L)] \left(\frac{L}{L + L_o} \right)$$

Further Publications on the Rigid-Base Model

Various permutations of the rigid-base model have been described by other authors. Some of these are described as follows.

The analytical solutions of high-order buckling modes (mode 3 and mode 4 in Fig. 5) of perfect straight pipeline were proposed by Liu et al. with the energy method (Liu et al. 2014). Further, Liu et al. performed a series of analytical studies on the high-order global buckling of pipelines with initial imperfection. For example, Hong and Liu (Hong et al. 2015) suggested that the pipeline with a single-arch initial imperfection would eventually take place the third-order global buckling

(Fig. 10) and proposed an analytical solution containing formulas for calculating the critical axial forces and buckling amplitudes of imperfect pipelines exhibiting buckling of mode 3. The analytical solutions of high-order lateral buckling for a pipeline with a single-arch symmetric (Fig. 10) and a two-arch antisymmetric initial imperfection (Fig. 11) are derived by Liu and Wang using the static equilibrium method (Liu and Wang 2018).

Many other researches have been done on imperfect pipelines, for example, Ballet and Hobbs (1992) investigated the possibility of asymmetric buckling in the prop case; Hunt and Blackmore (1997) studied the effects of asymmetric bed imperfections, typified by a step, and adopted a shooting method to solve the standard fourth-order linear ordinary differential equation; Maltby and Calladine (1995a) proposed a simple formula for the axial load at which the localization of buckling occurs based on sinusoidal imperfection assumption.

These authors report similar conclusions to those of Hobbs and Taylor. The presence of

Global Buckling of Offshore Pipelines, Fig. 11 Buckling of mode 4 triggered by a two-arch antisymmetric imperfection (Liu and Wang 2018)

small initial imperfections does not affect the minimum buckling load; and snap-through buckling will only occur for imperfections which are smaller than a certain critical size. For larger imperfections, the size of the buckling grows steadily as the temperature increases.

Global Buckling of Pipeline on a Deformable Foundation

The rigid-base analyses mentioned in the previous section employed idealized Coulomb friction forces; but real pipeline-seabed interaction can be much more complicated than this (Dingle et al. 2008). Measured pipeline responses on various soils have shown a high degree of deflection dependence. To deal with this problem, a beam on an elastic foundation of stiffness k per unit length is a preliminary to either lateral or upheaval buckling (Kerr 1974). The governing equation for this condition is described as Formula (16):

$$EI \frac{d^4 y}{dx^4} + P \frac{d^2 y}{dx^2} + ky = 0 \quad (16)$$

Subsequently, a modified version of the elastic-base model has been proposed by Tvergaard and Needleman (1980), in which the response of the soil is nonlinear. The governing equation for this condition is described as Formula (17), where $F(x)$ is a deflection-dependent function of the nonlinear pipeline-soil interaction:

$$EI \frac{d^4 y}{dx^4} + P \frac{d^2 y}{dx^2} + F(x) = 0 \quad (17)$$

The rationality of the deflection-dependent friction model depends on two main aspects: the correct expression of pipeline-soil interaction and the accurate solution of the governing equation. Various permutations pipeline-soil interaction models have been applied to this governing equation, and several solutions, such as nonlinear perturbation analysis, Galerkin method, and shooting method, have been proposed to solve the equation. Some of these are presented as follows.

Models with Nonlinear Soil Resistance

$$F = ky - cy^m$$

Hunt et al. (1989) analyzed the global buckling of elastic structures with bending stiffness EI , resting on a deformable foundation with a soil resistance $F = ky - cy^m$. The governing equation was proposed as Formula (18):

$$EI \frac{d^4 y}{dx^4} + P \frac{d^2 y}{dx^2} + ky - cy^m = 0 \quad (18)$$

where P is the axial load, y is the buckling displacement of the elastic structure, and k and c are constant coefficients; here the authors concentrate on the asymmetric form of $m = 2$.

The perturbation analysis was used for the solution of the governing differential equation, both periodic (constant amplitude) and modulated (varying amplitude) solutions.

If the nonlinear term is dropped from Eq. (18), it is a classical buckling problem with critical load (Van Der Meer 1985):

$$P^c = 2\sqrt{kEI} \quad (19)$$

A nonlinear perturbation scheme, reducing the differential Eq. (19) to an ordered sequence of linear equations, can be initiated with the series representations:

$$\begin{cases} y(x, X) = y_1(x, X)s + y_2(x, X)s^2 + y_3(x, X)s^3 + \dots \\ P = P^c + P_1s + P_2s^2 + P_3s^3 + \dots \end{cases} \quad (20)$$

where s is a perturbation parameter growing from zero with movement away from the critical point C. Knowing that C is an unstable symmetric point of bifurcation, it is convenient to set $s = \sqrt{P^c - P}$.

Substituting the expanded Eq. (20) into the nonlinear Eq. (18) and setting the coefficients of s, s^2 , etc. to zero gives an ordered series of sequentially linear differential equations in $y_1(x, X)$, $y_2(x, X)$, etc. (Thompson and Hunt 1973):

$$\begin{aligned} y(x, X) &= A(X) \cos(\omega x) \cdot s \\ &+ \left[\frac{1}{2} \frac{c}{k} A(X)^2 + \frac{1}{18} \frac{c}{k} A(X)^2 \cos(2\omega x) \right] \cdot s^2 \end{aligned} \quad (21)$$

where $A(X)$ is determined by Runge-Kutta solutions, as illustrated in Fig. 12. Both A and A' should lay on homoclinic orbits.

The buckling mode can be obtained by Formula 21 by setting buckling force $P = nP^c$ (n is less than 1). The results of buckling under the condition of $P = 0.98 P^c$ and the condition of $P = 0.95 P^c$ are shown in Fig. 13.

Many other investigators have studied the form in the presence of nonlinear term when they deal with the problem of structural buckling. For the form of nonlinear soil resistance $F = ky - cy^m$, Hunt et al. (1989) studied only the asymmetric case of $m = 2$; Whiting (1997) presented a Galerkin method for the symmetric case of $m = 3$; Zeng and Duan (2014) tackled the case of nonlinear terms covering both $m = 3$ and $m = 5$.

Global Buckling of Offshore Pipelines, Fig. 12 Homoclinic orbits

Further Publications on the Deflection-Dependent Friction Model

Furthermore, many nonlinear lateral soil resistance models, other than nonlinear soil resistance with the form of $F = ky - cy^m$, were applied to the governing equations of buckling of pipelines or elastic beam columns on deformable foundation. The solution to the governing differential equation was proposed based on nonlinear perturbation analysis, Galerkin method, shooting method, and so on.

For example, based on the research of Tvergaard and Needleman (1980), an exponential nonlinear soil resistance with the form of $F = Q_0(1 - e^{(v/\Delta)})$ (where Q_0 is the maximum soil resistance per unit length of the pipeline, Δ is the corresponding displacement of Q_0) was employed to obtain the analytical solutions of an imperfect pipeline by Maltby and Calladine (1995b).

Lagrange and Averbuch (2012) have studied the periodic solutions of a strut on a nonlinear elastic Winkler-type foundation with imperfection in the form of a sine shape. The nonlinear restoring force of the foundation was either a bilinear or an exponential profile. Piecewise solution theory was used to solve the governing equations for the bilinear restoring force. Piecewise solution theory was also employed by Karampour et al. (2015) to obtain the analytical solution to lateral buckling of pipelines with a deformable foundation.

In 2013, a new interpretation of localization was given based on an exponential restoring

Global Buckling of Offshore Pipelines,

Fig. 13 Perturbation solution for $m = 2$

force model in the form of $F = Q_0 \left[1 - e^{\left(\frac{v_0 - v}{\Delta} \right)} \right]$. The effect of initial imperfection on buckling behavior is also studied by analytical and numerical methods (Karampour et al. 2013).

Zhu et al. (2015) proposed a new approach for identifying the nonlinear behavior of pipelines under thermal loading. The lateral soil resistance was modeled by a hyperbolic function in their research, which didn't consider the influence of breakout resistance on the lateral buckling of unburied subsea pipelines.

Conclusions

Global buckling of an offshore pipeline operated at HP/HT can be described as a bar in compression. There are two main types of global buckling of submarine pipelines: lateral buckling and vertical buckling (named as upheaval buckling in some literature). A number of papers of analytical studies have been published on both the upheaval and lateral buckling of pipelines. According to Timothy C. Maltby (1992) and Miles (1998), the global buckling described in these published papers can be summarized into the global buckling of pipeline on rigid foundation (rigid-base model) and that on deformable foundation (deflection-dependent friction model).

Literature reviews imply that there are two main types of buckling model presented in the published material. The two types of buckling model stem from distinctly different assumptions. The rigid-base models take a buckle which has already been formed as a starting point and then attempt to find conditions for which, theoretically, the buckle occurs. In this model, the buckling configuration of the pipeline is assumed in advance. The soil resistance to pipeline is modeled by Coulomb friction coefficient regardless of the change of pipeline-soil interaction during pipeline displacement. On the one hand, the rigid-base model provides a useful model of the global buckling of pipelines as it enables the stable and unstable buckling configurations of pipeline to be calculated. On the other hand, the rigid-base model is unsatisfactory for the analysis of pipeline buckling, in practical engineering, due to the following two defects: The rigid-base model is unable to tell us anything about how buckling actually occurs since the buckling mode is assumed in advance. The Coulomb friction force in the rigid-base analyses is unable to reflect the relationship between the forces exerted on the pipeline by the soil and the pipeline displacement.

The deformable foundation models focus on the conditions when buckling occurs from the initial, possibly imperfect, shape. An important phenomenon in the case of a beam with multiple

imperfections is localization, where one imperfection grows at the expense of others; this is associated with a peak in the axial compressive force in the beam. In this model, the buckling configuration of the pipeline is not fixed and varies with the buckling force. The soil resistance to pipeline is modeled by deflection-dependent function of the deformable foundation. To some extent, the elastic foundation model overcomes the two main shortcomings of the rigid-base model. However, it involves increasingly complex numerical solutions which allow for various nonlinearities in the system but which appear to produce a broadly similar type of result to the standard rigid-base analysis.

The industrial studies demonstrate that there are significant problems associated with trying to obtain a single number for a coefficient of friction to be used either in design or in analysis. Behavior of pipelines on different soils is very complicated and is often different in the lateral and axial directions. Combined with the fact that a submarine pipeline is laid imperfectly (the imperfection sizes being unknown), an analysis of submarine pipelines which is simple, yet correlates well with real pipeline data, has proven to be a real challenge.

Definition

A GNSS Buoy is defined as a floating buoy equipped with a geodetic GNSS receiver and one or more antennae near-shore capable of measuring its position and velocity, and hence the instantaneous sea surface height can be attained. GNSS stands for Global Navigation Satellite System, and is the standard generic term for satellite navigation systems that provide autonomous geospatial positioning with global coverage

(<https://www.semiconductorstore.com/blog/2015/What-is-the-Difference-Between-GNSS-and-GPS/1550>). GNSS includes constellations of Earth-orbiting satellites that broadcast their locations in space and time, of networks of ground control stations, and of receivers that calculate ground positions by trilateration.

Scientific Fundamentals

The most prominent feature of a GNSS Buoy is the equipment of GNSS receiver and antenna with which the absolute three-dimensional position of the buoy, as a function of time, can be acquired, and thus the GNSS buoy is able to provide the time series of absolute water level height as well as its horizontal coordinates. So it is necessary to introduce GNSS before the working principle of GNSS buoy is introduced.

GNSS Systems

GNSS is a term used worldwide and includes several global and some regional systems. Common GNSS Systems are GPS, GLONASS, Galileo, Beidou, and other regional systems. The advantage to having access to multiple satellites is accuracy, redundancy, and availability at all times. Though satellite systems do not often fail, if one fails GNSS receivers can pick up signals from other systems. Also if line of sight is obstructed, having access to multiple satellites is also a benefit (<https://www.semiconductorstore.com/blog/2015/What-is-the-Difference-Between-GNSS-and-GPS/1550>).

GPS was the first GNSS system. GPS was launched in the late 1970s by the United States Department of Defense. It uses a constellation of 27 satellites, and provides global coverage. GLONASS is operated by the Russian government. The GLONASS constellation consists of 24 satellites and provides global coverage. Galileo is a civil GNSS system operated by the European Global Navigation Satellite Systems Agency (GSA). Galileo will use 27 satellites with the first Full Operational Capability (FOC) satellites being launched in 2014. The full constellation is planned to be deployed by 2020. BeiDou is the

Chinese navigation satellite system. The system will consist of 35 satellites. A regional service became operational in December of 2012. BeiDou will be extended to provide global coverage by end of 2020 (<https://www.novatel.com/an-introduction-to-gnss/chapter-1-gnss-overview/section-1/>).

GNSS Architecture

GNSS satellite systems consist of three major components or “segments”: space segment, control segment, and user segment. These are illustrated in Fig. 1 (<https://www.novatel.com/an-introduction-to-gnss/chapter-1-gnss-overview/section-1/>).

The space segment consists of GNSS satellites, orbiting about 20,000 km above the earth. Each GNSS has its own “constellation” of satellites, arranged in orbits to provide the desired coverage, as illustrated in Fig. 2. Each satellite in a GNSS constellation broadcasts a signal that identifies it and provides its time, orbit, and status.

The control segment comprises a ground-based network of master control stations, data uploading stations, and monitor stations; in the case of GPS, two master control stations (one primary and one backup), four data uploading stations, and 16 monitor stations, located throughout the world. In each GNSS system, the master control station adjusts the satellites’ orbit parameters and onboard high-precision clocks when necessary to maintain accuracy. Monitor stations, usually installed over a broad geographic area, monitor the satellites’ signals and status, and relay this information to the master control station. The master control station analyses the signals and then transmits orbit and time corrections to the satellites through data uploading stations.

The user segment consists of equipment that processes the received signals from the GNSS satellites and uses them to derive and apply location and time information. The equipment ranges from smartphones and handheld receivers used by hikers, to sophisticated, specialized receivers used for high-end survey and mapping applications.

G

Global Navigation Satellite System (GNSS) Buoy,

Fig. 3 GNSS user equipment (<https://www.novatel.com/an-introduction-to-gnss/chapter-1-gnss-overview/section-3/>)

User Equipment

The primary components of the GNSS user segment are antennas and receivers, as shown in Fig. 3 (<https://www.novatel.com/an-introduction-to-gnss/chapter-1-gnss-overview/section-3/>). Depending on the application, antennas and receivers may be physically separate or they may be integrated into one assembly. The GNSS equipment of antenna and receiver make GNSS buoy distinguished from other type of buoys.

GNSS antennas receive the radio signals that are transmitted by the GNSS satellites and send these signals to the receivers. GNSS antennas are available in a range of shapes, sizes, and performances. The antenna is selected based on the application. While a large antenna may be appropriate for a base station, a light weight, low-profile aerodynamic antenna may be more suitable for aircraft or unmanned aerial vehicles (UAV) installations.

GNSS receivers process the satellite signals recovered by the antenna to calculate position and time. Receivers may be designed to use signals from one GNSS constellation or from more than one GNSS constellation. Receivers are available in many form factors and configurations to meet the requirements of the varied applications of GNSS.

GNSS Positioning

GNSS positioning is based on a process called “trilateration.” Simply put, if you do not know your position, but do know your distance from three known points, you can trilaterate your location. A GNSS receiver knows where each satellite is in its orbit and compares it with the time required to receive each satellite’s signal. The receiver uses these measurements to calculate its specific position on Earth.

A GNSS receiver can only track satellites orbiting above the horizon. Typically there are between 6 and 12 satellites visible above the horizon at any one time. The receiver will try to track all visible satellites. If some satellites become blocked or “shaded” by tall buildings or other major obstacles, the receiver automatically will try to reacquire the blocked signals. Although a GNSS receiver needs at least four satellites to provide a three-dimensional solution (latitude, longitude, and altitude), it can maintain a (latitude-longitude) position using three satellites (<https://hemispheregnss.com/Resources-Support/About-GNSS-Technology>).

GNSS constellations are designed to provide worldwide positioning services with an accuracy ranging from 5 to 15 meters. More precise accuracies are not possible with standard GNSS due to minor timing errors and satellite orbit errors, plus atmospheric conditions that affect the signals and their arrival time on Earth. However, there are ways to improve GNSS accuracy using additional services. There are four primary services available, each capable of improving position accuracies to better than one meter (<http://www.unoosa.org/oosa/en/ourwork/psa/gnss/gnss.html>):

- Radiobeacon differential GPS (DGPS) corrections.

- Space-Based Augmentation Systems (SBAS), including the United States’ Wide Area Augmentation System (WAAS), Europe’s EGNOS, Japan’s MSAS, and India’s GAGAN.
- Privately owned “L-band” satellites.
- Real-time kinematic (RTK) positioning.

Among the above services, the RTK is a technique that uses carrier-based ranging and provides ranges (and therefore positions) that are orders of magnitude more precise than those available through code-based positioning. RTK techniques are complicated. The basic concept is to reduce and remove errors common to a base station and rover pair, as illustrated in Fig. 4 (<https://www.novatel.com/an-introduction-to-gnss/chapter-5-resolving-errors/real-time-kinematic-rtk/>).

Working Principle of a Typical GNSS Buoy

In this section, we will take a recent example of a GNSS buoy of Taiwan for monitoring the water surface elevation to show the working principle of a general GNSS buoy. The buoy can observe water surface elevations and provide real-time tide and wave data in estuaries and coastal areas without establishing an RTK reference station.

Instrumentation

Figure 5 shows the working principle of the GNSS buoy. It can be seen that the buoy utilizes a Virtual Base Station (VBS) combined with the RTK positioning technology and the buoy includes a buoy hull, an RTK GNSS receiver, data-transmission devices, a data logger, and General Purpose Radio Service (GPRS) modems for transmitting data to the desired land locations. The GNSS receiver receives signals from satellites and calculates positions. The position data are then transmitted to the VBS-RTK control center by a GPRS modem in a GGA sentence that includes, among other information, the GPS time, latitude, and longitude. Figure 6 presents the snapshot of the GNSS buoy deployed in the waters of Suao, Taiwan Lin et al. (2017).

Methodology

In the buoy development, the VBS-RTK positioning technology was adopted to determine the

Global Navigation Satellite System (GNSS) Buoy,

position of the buoy. VBS-RTK stands for Virtual Base Station Real-Time Kinematics. The procedure of VBS positioning includes pre-process network observations, calculating data from regional stations, generating VBS data for the rover, and calculating the coordinate of the rover station. The VBS-RTK system consists of three components: a GNSS base station network, control center, and rover station. Their functions are as follows Lin et al. (2017):

1. GNSS base station network: Each base station receives GNSS observation data and transmits raw data to the control center continuously.
2. Control center: The VBS-RTK control center is for positioning computation and the commercial software developed by Trimble Navigation is run in the center. The functions of the software are as follows:
 - Connecting the control center and each reference station to enable the automatic receipt, storage, and compression of observations from each reference station.
 - The software not terminating the receipt or compression of satellite signals from reference stations during data download.
 - Monitoring the status of the GNSS receiver of each reference station. The GNSS receiver parameters may be configured including the cutoff angle and sampling interval, etc.
 - According to the carrier phase observations, the software calculates continuously the error caused by the multipath, the ionosphere, troposphere, and ephemeris, as well as the integer ambiguity of the carrier phase of L1 and L2.
 - Generating VBS data in Radio Technical Commission for Maritime Services (RTCM) format and transmitting them to the rover station.
3. Rover station: The rover station is a GNSS buoy with a GNSS receiver and a GNSS antenna attached to it.

Thus, the water surface elevation can be obtained from the position data of the GNSS buoy.

Key Applications

GNSS Buoy Application Fields

The applications of GNSS Buoy systems include absolute calibration of satellite altimeters, observing oceanic phenomena such as water surface height, coastal circulation, ocean tide studies, and other coastal applications. For example, in the area where the GNSS buoy system is used to calibrate satellite altimeters, its size could range from a small life-saver type with the receiver and power supply on the tethered boat to big, ruggedized types that accommodate all of the equipment as well as the other sensors providing its orientation and meteorological and auxiliary data for long-term deployment. It could require dedicated personnel for a campaign style design while it could also be an autonomous design that transmits its observations automatically to the base station in the vicinity. GNSS buoys have been implemented for altimeter in the past showed the equivalent ssh measurements between a waverider and a spar design for altimeter absolute calibration.

For the observations of oceanic phenomena, GNSS buoys have demonstrated in bathymetry mapping, in wave height observations and sea state determination, and in wave height spectrum analysis. It can also be used to determine absolute sea surface and mean lake surface height gradient.

In addition, the GNSS buoy can be used in geodetic applications in the coastal region. For example, a height modernization project performed by the National Geodetic Survey (NGS) seeking the use of GPS data on land and oceans to improve the determination of local geoid height and thus to promote GPS applications on measuring elevation, which is traditionally done by spirit leveling. With the continuous improvement of GNSS measurement processing capabilities and computer processing power, GNSS buoys can now be used in oceanography, hydrography, tide gauging, and more Cheng (n.d.).

Examples of French GNSS Buoys

The use of GNSS buoys in the field of oceanography began in the 1990s. Australia, the USA, and France were among the pioneering countries (<http://refmar.shom.fr/documentation/>

[instrumentation/bouee-gnss](#)). In France there are four types of GNSS buoys in use today.

OCA-Géoazur/CNES Buoy

The GNSS Buoy at the Cote d'Azur Tide Station/ Centre National d'Etudes Spatiales (CNES) was the first to be installed in France. By the late 1990s, measurement campaigns were regularly conducted off Ajaccio in order to calibrate the

satellite altimetry missions of Topex-Poseidon and Jason-1 and Jason-2.

IPGP Buoy

The GNSS buoy of the Institut de Physique du Globe de Paris (IPGP) is substantially identical to the OCA-Géoazur/CNES buoy. But it is used for quite a different purpose. The GNSS buoy provides data that are compiled with other data, including pressure measurements on the seabed, in order to study the vertical deformation of the seabed related to seismic activity. Today we cannot globally map (in the marine environment) deformations of the Earth based on satellite signals alone. Ongoing studies aim to circumvent this problem. IPGP buoy is shown in Fig. 7 (<http://refmar.shom.fr/documentation/instrumentation/bouee-gnss>).

Global Navigation Satellite System (GNSS) Buoy, Fig. 7 IPGP buoy (<http://refmar.shom.fr/documentation/instrumentation/bouee-gnss>)

LEGOS/DT-INSU Buoy

The GNSS buoy of the Laboratoire d'Études en Géophysique et Océanographie Spatiales (LEGOS) built by the Institut National des Sciences de l'Univers (INSU) consists of three floats composing the vertices of an equilateral triangle, with the GNSS antenna placed at center of gravity. The LEGOS/DT-INSU GPS buoy is used to monitor instrument drift on tide gauges composing the ROSAME network. Because the ROSAME stations are located in the French Southern and Antarctic Lands, there are strict specifications on the weight and size of the unit. Figure 8 shows the picture of LEGOS/DT-INSU buoy.

Global Navigation Satellite System (GNSS) Buoy,

Fig. 8 LEGOS/DT-INSU buoy (<http://refmar.shom.fr/documentation/instrumentation/bouee-gnss>)

Global Navigation Satellite System (GNSS) Buoy, Fig. 9 SHOM buoy (<http://refmar.shom.fr/documentation/instrumentation/bouee-gnss>)

SHOM Buoy

The SHOM buoy is closer in shape to the LEGOS/DT-INSU buoy, with a base forming an equilateral triangle with a float at each end. However, it is larger and forms a tetrahedron with the geodetic antenna placed at the top of the last vertex, out of the water and up in the air.

The two models do not have the same constraints. The SHOM buoy seeks to achieve floating stability vis-à-vis the chop and swell. The GNSS antenna is raised above the waterline to avoid multipath as much as possible. Multipath produces adverse reflection effects during the acquisition. The SHOM buoy is shown in Fig. 9.

Definition

Green tides are ecological disasters in which massive biomass of one or multiple green seaweed species accumulates in either shallow coastal or open waters, forming drifting canopies and harming the local environment and ecosystem.

Scientific Fundamentals

Green tides are vast accumulations of unattached green macroalgae in either coastal or open waters, causing significant detrimental environmental impacts. As a type of harmful algal blooms (HABs), green tides differ from the other HABs (e.g., red tides, brown tides, and golden tides) obviously with the blooming species, which are predominated by one or multiple green macroalga species. Green microalgae or cyanobacteria blooms (e.g. microcystis blooms in Taihu Lake, China), although, in green color, are blooms of single-cell microalgae, which do not fall into the category of green tides. The green tide is increasing globally, especially along the coasts of America, Europe, and the Asia-Pacific, since the 1970s

(Ye et al. 2011 and references herein). The massive green seaweed thalli detached from the natural seaweed beds are proliferating and accumulating in the eutrophied estuaries, coasts, and bays nearby. They usually comprise multiple ephemeral green macroalgal taxa and even a few brown or red seaweed species and show evident species succession during blooming. These green tides (named as “local green tides” to differentiate with the “trans-regional green tides” below) are restricted in the shallow photic zone of the near-shore water (Fig. 1a) and barely intrude into the open waters.

In 2008, astonishing large-scale drifting canopies of *Ulva prolifera* inundated along the coasts of Qingdao, threatening the sailing regatta of the Beijing Olympics. Satellite remote-sensing indicated that the drifting green mats were widespread throughout the southwestern Yellow Sea (YS) and were probably initiated from the southwestern coast of YS. The large-scale green tide in YS (GTYS) recurred since then and is recognized as the world’s largest green tide in terms of its distribution, coverage, and total biomass produced (Fig. 1b). Compared to the local green tides, GTYS is featured by a single causative species (*U. prolifera*), nonlocal origin of the floating biomass, long-distance transportation, and the cross-regional impacts (Liu and Zhou 2018).

Blooming Species

The causative species of the green tides are quite diverse (Table 1). Although some green tides

comprised a few red (Division Rhodophyta) and/or brown (Division Phaeophyta) macroalgae species, the blooming biomass is usually dominated by the green macroalgae (Chlorophyta, Ulvophyceae) and mostly shows green color (which the green tide is named after). A high number of bloom-forming species belong to the genus *Ulva*, including the former *Enteromorpha*. The genus *Ulva* is species-rich, comprising over 100 species. They are cosmopolitan and could be found in almost every littoral waters. The *Ulva* spp., including *U. prolifera*, *U. intestinalis*, and *U. australis* (reported as *U. pertusa*), formed nuisance green tides along the coasts of Europe, N. and S. America, Australia, and Asia. *U. prolifera*, for example, is responsible for the large-scale green tide in YS, which has been persisting for over a decade. *Ulva* spp. also dominated the green tides in Brittany, France, and the Venice Lagoon, Italy. A number of other taxa, such as *Gracilaria* (Rhodophyta; Gracilariaceae) and *Pylaiella* (Ochrophyta, Phaeophyceae) etc., are also involved in massive green tide events worldwide (Table 1).

Blooming Dynamics

Causes

Abiotic Factors Among the various environmental factors, eutrophication is the most important cause for the green tides. The increasing green tides in the temperate zone of N. America, Europe,

Rhodophyta, Florideophyceae	Gracilariaceae	<i>Gracilaria tikvahiae</i>	SE Florida, Waquoit Bay of MA, Hog Island, USA;	Hauxwell et al. 2001 ; Charlier et al. 2007 ; Teichberg et al. 2008
		<i>Gracilariopsis lemaneiformis</i> (reported as <i>Gracilaria lemaneiformis</i>)	Bohai Sea, China	Song et al. 2019 ;
		<i>Gracilaria</i> spp.	Venice Lagoon, Italy; Mondego estuary, Portugal; Brittany, France; Gulf of California, Mexico; Waquoit Bay, USA;	Valiela et al. 1997 ; Charlier et al. 2007 ; Teichberg et al. 2010 ; Cardoso et al. 2004
	Rhodomelaceae	<i>Yuzurua poiteaui</i> (reported as <i>Laurencia poitei</i>)	SE Florida, USA; Bermuda	
Ochrophyta, Phaeophyceae	Acinetosporaceae	<i>Pylaiella littoralis</i> (reported as <i>Pilayella littoralis</i>)	Maasholm Bay, Germany; Massachusetts Bay, USA; N. Baltic Sea, Finland	Valiela et al. 1997 ; Lotze et al. 2000 ; Berglund et al. 2003
		<i>Pylaiella</i> spp. (reported as <i>Pilayella</i> spp.)	Nahant Bay, USA; Maasholm Bay, Germany	Valiela et al. 1997 ; Teichberg et al. 2010

^aThe nomenclature of taxa is based on WoRMS (<http://www.marinespecies.org/index.php>, accessed on June 5th, 2021)

^bThe genus *Ulva* included the former *Enteromorpha* (Hayden et al. 2003)

and Asia are coincident with the rapid population growing and urbanization along these coasts. The significant nutrient input (especially N) from river discharge, wastewater sewage system, and costal aquaculture has driven the coastal eutrophication, which causes a series of ecological changes (including green tides). The green tide in Finland, for example, continued every summer between 1992 and 2000, and the Gulf of Finland is one of the most heavily eutrophied areas in the Baltic Sea, receiving 138 million kg nitrogen and 7.6 million kg phosphorus annually (Lappalainen and Pönni 2000).

Physiological advantages of these green tide species could boost the green tides dominating by one or a few ephemeral species under the general eutrophication environment. Both field and laboratory experiments revealed multiple physiological advantages of these bloom-forming species (Table 1), such as high nutrient assimilation, fast photosynthesis and growth, and strong buoyancy ability, compared to the non-bloom-forming taxa (Teichberg et al. 2008; Fu et al. 2019). These physiological traits assist the rapid tissue expansion and biomass proliferation and hence dominate the green tide in response to the increased nutrient supplies. The selective pressure in green tide areas leads to the amplification of *Ulva* genotypes best adapted for this environment (Fort et al. 2020). This also explains why the green tides comprise only a few species, while higher species diversity is usually accounted for the benthic macroalgae community. Such selection of fast-growing strains indicates that green tides are likely to persist in the near future if the eutrophic condition wouldn't change.

The other abiotic factors, such as light availability, salinity, and seawater temperature, may also be involved in determining species composition of the green tide at specific locations. For example, the green tides in Washington State, USA, are dominated by *Ulva* spp. in intertidal zone, while *Ulvaria* is abundant in subtidal. Physiological comparison shows that *Ulvaria* is relatively euhaline, so it is abundant in the subtidal water, where the salinity is more stable, while absent or less common in the lower-salinity portions of estuaries (Nelson et al. 2008).

Biotic Factors Besides the various environmental factors, a number of biotic factors, such as propagule bank, grazers, etc., could also regulate the population development and dominance patterns of the green tides. Propagules are microscopic forms of macroalgae, which function as “seed banks” (like terrestrial plants) for the recruitment in the following vegetation period (Lotze et al. 2000). The propagule bank allows macroalgal populations to persist through unfavorable conditions and sudden disturbances in a variable environment. Although the propagule bank is the important overwinter mechanism for macroalgae, the abundance of recruitments may not directly correlate with the quantity of propagules since the environmental conditions could interact with propagule source and regulate the abundance and species composition of recruitments. For example, the field experiments in Baltic Sea showed that the rocky substrata favor recruitments of *Ulva* instead of *Pylaiella* (reported as *Pilayella*) when propagules of both species are present (Lotze et al. 2000).

Grazers or disturbance on trophic cascade is another important biotic component in controlling the abundance and community structure of littoral macroalgal. As indicated by a series of field observations, abundance herbivores at lower trophic level is directly linked to the density and community structure of the benthic macroalgae through selective consumption (Lotze et al. 2000). This top-down effect could be more complicated when higher trophic levels are taken into account and various interactions are involved. In Baltic Sea, for example, abundance of piscivorous fish had a strong negative correlation with the bloom-forming macroalgae, while depleted top-predators displayed massive increases of ephemeral algae (Eriksson et al. 2009). The following field experiments indicated that excluding larger piscivorous fish resulted in increased abundance of small-bodied predatory fish, decreased the smaller gastropod scrapers, and ultimately increased the abundance of ephemeral macroalgae (Eriksson et al. 2009).

Anthropogenic Disturbance The influencing factors listed above are somehow related to the

anthropogenic disturbances (e.g., terrestrial nutrient input, overfishing, etc.), representing the profound but indirect impacts from the anthropogenic activities on the coastal ecosystems. More recent studies revealed that anthropogenic activities in the coastal regions may directly contribute for or stimulate the biomass expansion and bloom development of green tides. The best case is the large-scale green tide in YS (GTYS). A series of research have confirmed that the substantial green macroalgal wastes disposed from the *Pyropia* aquaculture rafts are the primary source of the initial floating macroalgae, which is transported out of the original region and latterly develops into large-scale green tide in western YS (Wang et al. 2015). Although various biochemical and geophysical factors, such as high photosynthetic and growth rates of *U. prolifera*, high nutrient level of the seawater, northward seasonal monsoon and surface circulation, etc. are involved in the bloom development, the anthropogenic activities (detaching and disposing the green macroalgae) are considered to be the direct culprit stimulating detachment of green macroalgae, which subsequently drift and develop into the million tons of floating biomass with favorable environmental conditions (Zhou et al. 2015).

The cause for each individual green tide is actually quite complicated and distinct among the green tides in different regions. Not a single factor alone could directly stimulate the green tides, especially those persisting over the years. Multiple biotic and abiotic factors often interact with each other to regulate the abundance and structure of the coastal macroalgal communities and hence drive the continuous green tides. Beside the eutrophication prevalent along the coasts globally, specific biotic or anthropogenic disturbances (e.g., aquaculture, loss of predatory, etc.) may trigger the cascade effects to boost or enhance the green macroalgal blooms.

Seasonality

Due to the significant temperature variation at different latitudes, bloom season of the green tides could vary from early spring to early summer, but they usually occur when the sea surface temperature increases rapidly and persist for 1 to

4 months. For example, drifting bands of *U. prolifera* in YS could be observed as early as April in Subei Shoal based on the shipboard field survey. The floating biomass then drifts out of the shoal and is widespread in western YS. The green tides are quite persisting along the coasts of Shandong Province and even last until early September in 2019. The duration of the green tides in YS could reach to over 100 days based on the remote-sensing (MNR, 2008–2020), which may be underestimated since satellite remote-sensing can barely detect the floating bands in the turbid Subei Shoal.

The environmental parameters of the blooms, such as seawater temperature, salinity etc., vary significantly depending on the blooming species and geographic locations. It often lies within the range favored by the blooming species. Most *Ulva* spp. bloom between 15 °C and 25 °C along the temperate coasts, while some species (e.g., *U. intestinalis*) could bloom once the ice melts in the N. Baltic Sea (around 60°N).

Blooming Process

The development processes of the blooms are diversified at different locations. As described above, local green tides often comprised multiple macroalgae species and show evident species succession in response to the environmental gradients (e.g., nutrient, seawater temperature, etc.) at different locations of the blooming region or different stages of the blooms. The green tide in Bohai Sea, for example, started to appear in late April, reached the peak in July and August, and declined rapidly in September. The entire blooming process could be divided into three phases based on the dominant species: I, Low biomass was dominated by *Ulva australis* (reported as *U. pertusa*) from April to mid-May; II, the growing biomass was dominated by the red algae *Bryopsis plumosa* from late May to mid-June; III, green seaweed *U. prolifera* proliferated rapidly since late June and became dominated, and the biomass of *U. prolifera* along with the other two common species *B. plumosa* and *Gracilariopsis lemaneiformis* (reported as *Gracilaria lemaneiformis*) reached the peak until mid-September (Song et al. 2019). Nelson et al. (2008) examined the green tides in

Washington State, USA, and found the blooms are often dominated by *Ulva* spp. intertidally and *Ulvaria obscura* subtidally. The environmental factors, such as nutrient availability, grazers, and light attenuation, influence the species assemblage of the local green tides. Bottom-up factors allow *Ulva* to dominate the intertidal zone, while resistance to grazers appears to allow *Ulvaria* to dominate the subtidal zone.

The genesis and development of the green tide in YS (GTYS) are quite different with the local green tides. The single species, *U. prolifera*, proliferates rapidly once the detached thalli drift into the coastal water and dominates the floating biomass in the Subei Shoal. A series of biological, geochemical, and physical processes are involved in the subsequent transportation and spreading of the floating *U. prolifera* in western YS. Based on the decadal field surveys, the floating green macroalgal bands are initiated in late April to early May in the shallow water of Subei Shoal,

close to the raft region. With the strong buoyancy and growth abilities, *U. prolifera* dominates the floating biomass rapidly with a few sympatric *Ulva* spp. detected sporadically (<10%, Wang et al. 2015). The biomass of floating *U. prolifera* amplifies with increasing seawater temperature and drifts out of the shoal with strong tidal force and sea surface currents in May and June. They develop into large-scale floating mats in open water of western YS (Fig. 2) and further drift northwardly assisted by the seasonal monsoon and the resulted northward surface circulation. As a result, million tons of floating *U. prolifera* biomass reach the south coastline of Shandong Peninsula in late June to early July and could persist for over a month.

Impacts

Tons of green macroalgae are piled up in the shallow coastal waters, smothering the shoreline, harming the coastal aquaculture, and affecting the

Green Tides, Fig. 2 Spatial and temporal development of floating green algal biomass in 2012 based on the shipboard survey. The black ovals denoted the major

distribution and the drifting patterns of the floating biomass within each survey period. (Wang et al. 2015)

local tourism and recreational activities. Significant economic losses directly resulted not only from the large cost for removing the beached biomass and waste treatment but also from the losses of coastal aquaculture. The green tide in YS, for example, caused large mortality of cultured *Apostichopus japonicus*, *Placopecten magellanicus*, etc. along the coasts of Shandong Province in 2008, which resulted in losses of 800 million RMB (Ye et al. 2011). In addition to these evident economic losses and social impacts, persisting green tides have profound and long-lasting effects on the coastal ecosystems.

Although mostly nontoxic to humans, degrading morass of green tides can produce toxic hydrogen sulfide (H_2S) and a few bloom-forming *Ulva* spp. are likely to produce toxins. H_2S gas from rotting *Ulva* biomass on a Brittany Beach caused the death of a horse in 2009 and death of around 30 wild boars in 2011 (Smetacek and Zingone 2013). Some green tide-forming *Ulva* spp. have been confirmed to be allelopathic to *Fucus* zygote, oyster larval, sea urchins, and herbivore invertebrates, which suggested possible toxins from these species (Nelson et al. 2003; Van Alstyne et al. 2007).

A series of deleterious ecological effects included increasing light attenuation, altering nutrient biogeochemical cycling, inducing hypoxia to anoxia at the sediment interface, and hence changing the benthic vegetation and macrofauna. In Waquoit Bay, MA, USA, higher N estuary and the subsequent increase of green macroalgal biomass caused decline of eelgrass *Zostera marina* (Hauxwell et al. 2001). In Åland Island, Finland, drifting macroalgae dramatically altered the abundance and species composition of the macrofauna, with mainly opportunistic and mobile taxa such as *Hydrobia* spp., Chironomidae, and Ostracoda benefiting from the algae, whereas infaunal species such as *Macoma balthica* and *Bathyporeia pilosa* are negatively affected (Norkko et al. 2000).

Key Applications

Monitoring Technologies

Monitoring or surveys are important for understanding the blooming pattern and underlying

mechanism. According to the different objectives of each research project, monitoring could be quite diverse on method, technology, and even subject. Overall, two monitoring approaches are often adopted: on-site survey and remote-sensing monitoring. The former is used to monitor the benthic seaweed beds (source biomass), floating biomass at specific locations, and the various detaching and blooming processes, which could provide the detailed information on abundance, species composition, and the other related biological and environmental conditions contributing for the blooms. The latter is used to detect the drifting macroalgal mats in open waters and currently is the most important approach to estimate the distribution and coverage of the trans-regional green tide in YS.

To evaluate the potential source biomass of the green tides, scuba diving and random sampling are often carried out to quantify the abundance and species composition of the attached green macroalgae. Depending on the various attaching substrata, abundance of the benthic green macroalgae could be quantified as g m^{-1} (for the green macroalgae attached on the ropes and bamboos of aquaculture rafts) and g m^{-2} (for the macroalgae on benthic seaweed beds). Species of green macroalga is identified based on the gross morphology and molecular sequencing. A few rapid identification methods (e.g. RFLP and FISH) are recently developed to assist fast batch identification (Xiao et al. 2013; Zhang et al. 2015). On-site survey on the floating biomass is also important for monitoring the blooming dynamics and evaluating the severity and size of the green tides. The floating biomass could be surveyed through bio-trawling, in which a phytoplankton net is towed through the water column to collect the green macroalgal biomass in the certain volume or area of the seawater. The abundance is then calculated as fresh wet weight of floating biomass per volume or area (g m^{-3} , g m^{-2}).

Remote-sensing is to detect and track the floating green macroalgae through multisource images of imagery instruments, such as optical satellites (e.g., MODIS, GOCI, Landsat TM, HJ-1 A/B-CCD, Gaofen-1, and Sentinel-2), microwave ENVISAT-ASAR, and airborne synthetic-

aperture radar (SAR). Through satellite optical images, the floating macroalgae pixels can be differentiated from the surrounding water and thus delineated using the various vegetation indices, such as NDVI (normalized difference vegetation index), FAI (floating algal index), and SAI (Scaled Algae Index). These technologies provide the time series of distribution and coverage of the floating green macroalgal mats, which are currently popularly used to indicate the size of the large-scale green tide in YS. Distribution is estimated as the smallest geographic area that encloses all floating-algae pixels. The coverage is the cumulative sea surface area pure covered by the floating-algae pixels, which is computed by multiplying the pixel size (e.g., $250 \times 250 \text{ m}^2$ for MODIS and $30 \times 30 \text{ m}^2$ for Landsat TM and HJ-1 CCD) with the number of identified macroalgae pixels. Due the resolution limitations and restrict requirements on weather conditions, these aeronomy remote-sensing technologies are probably not suitable for monitoring the local green tides. But some low-altitude (high-resolution) remote-sensing, such as airborne SAR, unmanned aerial vehicle (UAV), etc., can assist the field surveys on the geographic scale and abundance of the local green tides (Cui et al. 2018; Xing et al. 2019).

Containment Measures and Bioconversion

Control and prevention are complicated since the genesis of each individual green tide involves a series of cascade processes which are influenced by various biogeochemical factors as described above. In response to the eutrophication as the primary cause for the green tides worldwide, measures such as decreasing the nutrient input, increasing water flushing, etc. are requested to alleviate the eutrophication problem and hence abate green tides. These measures, however, require long-term efforts on waste treatments, coastal ecosystem restoration, and balancing the economy development and environment protection. Removal of blooming biomass is absolutely necessary to avoid nutrient pollution and possible toxic effects on coastal waters and benthic organisms. And the proper treatments and

bioconversion are also critical after the algae are harvested; otherwise, the aquatic pollution would turn into a land pollution. The harvested algae can be turned into fertilizer, mixed with waste to be composted, dehydrated and mixed into poultry and aquaculture feed, and processed as food and have sometimes been used as a fuel (Charlier et al. 2007). A series of technologies, such as methanization, hydrolysis, and pressing, are developed to stabilize and assist the efficient bioconversion of the harvested algae. Along with the significant increase of the massive green tides throughout the world, various firms and laboratories are devoted into or even established to transform this gross biomass into commercially valuable bio-resources. They included a number of private companies, such as GOEMAR, SECMA, and PHYTOMER, in Europe and Qingdao Seawin Biotech Group (Seawinner®) in China (Charlier et al. 2007; Ye et al. 2011). The fertilizer line of Seawinner, for example, can consume 10,000 metric tons fresh *U. prolifera* per day.
